All this was pleasant enough, and there was no reason to suppose at this time that Florence Nightingale would do otherwise than fulfil the expectations of her parents, and be content to live out the life of a happy English girl, and later, perhaps, become the wife of some good and worthy man. It was only after their return to England, and a short London season, when they were settled again in the midst of the busy hospitality of their country home, that a sense of the inadequacy of the social pleasures and domestic joys that surrounded her came upon her. It was to increase with the years, until, long before she attained her freedom, she struggled against the restrictions that bound her, with all the restlessness of a caged bird. The very happiness of the home that sheltered her, and the warmth of its affections, were gilded bars against which she almost broke her heart. To understand the nature and the greatness of this part of Miss Nightingale's achievement, that consisted in surmounting the obstacles that lay in the way of her preparation, one must project oneself in imagination into the age in which she lived, seventy years ago, when it was an unheard-of thing for a beautiful and accomplished girl to do anything outside of the precincts of her home. Her mother and sister, affectionate as they were, did not even understand her impulse, and when at last it formulated itself into a distinct sense of a vocation to care for the sick, as it did when she was twenty-five, they felt towards it a real disfavor. Nor can one blame them, remembering the low standards of hospital life of those days and the degraded type of nurse. She was an affectionate and dutiful daughter, and yielded to her parents' wishes for many years, doing her best to be happy and to make others happy, in what was to her a ceaseless round of trivialities, and often suffering intensely from the sense of frustration of her higher self. For, in addition to the fact that there were great powers of organization and execution fermenting in her mind, which at that time had no outlet, and that she was swayed by a really passionate altruism, Florence Nightingale was distinctly conscious, as much so as any other saint in history, of a "call to be a saviour," as she expresses it more than once in her diaries. In an autobiographical fragment, written in 1867, she mentions February 7th, 1847, at Embury, as the day when "God called me to His service," and several times this period is referred to as one of the chief crises of her inner life. It was the sense of defect in this inner call during these years, and the manner in which she suffered from it. Her father was a Unitarian, but she and her mother and sister followed the usages of the Church of England. Later in life, when she had been married, she was very broad, and her religious views were formed by the influence of her husband's personal faith, and the influence of the

her life this deeply religious attitude of mind, and this fact must be recognized in any true estimate of her life and work. In no other way is to be explained her humility of spirit, which may be likened to that of St. Francis of Assisi,

PLATE IV. MISS NIGHTINGALE (ABOUT 1845).

and her dislike of public acknowledgment, which sprang not only from natural modesty, but from an inner principle.

It was with an affectionate hope of distracting her from her tiresome purpose, and with an entire lack of sympathy in her feeling, that her mother and sister planned and arranged several continental trips for her with congenial friends. The winter of 1847 was spent in Rome, with her friends the Bracebridges, who afterwards served with her in the Crimea. It was an eventful year for the future of her desire in more than one respect. In Rome she met the Sydney Herberts, and began that friendship with Lord Herbert, that was so fruitful in great results in the Crimea and after. And she became intimate with and studied the methods of an Italian nursing sisterhood. Moreover, it was a time of great happiness in other ways, for her appreciation of the beautiful was intense. The Sistine Chapel came to her as a revelation, and remained as one until the end of her life. Her description of it is exquisite.

The winter of 1849-1850 she again spent travelling, this time in Egypt and Greece. It was at Athens that she picked up a baby owl that had fallen among the ruins of the Parthenon. She carried it in her pocket, and brought it home to Embley, where it lived for years. A small tragedy of her departure for the Crimea, was that the family, in leaving town to see her off, forgot to feed the owl, which was dead on their return. The portrait of Lady Verney (Plate V) shows the owl on the pedestal beside her, and it is carved, too, on the foot of the Derby memorial statue.

It was on her way back to England from Greece, on July 31, 1850, that she first visited the Deaconesses Institute at Kaiserwerth on the Rhine. This had been the goal of her desires for the last six years, and repeatedly her hopes to see it had met with disappointment. It was a Protestant Sisterhood, organized by Pastor Fliedner and his wife, for the care of the sick poor, and discharged prisoners, and for the education of orphans, along lines which ap-

pealed intensely to her. The deaconesses took no vows, but came voluntarily, because they felt a vocation. She spent a fortnight in the institution then, and returned the following summer (1851), the free consent of her parents having

at last been obtained, for three months' training. In the hard work, long hours, and ascetic simplicity of the life, as well as in the high-minded admonitions of the pastor, she took the deepest delight, and pronounced herself at last "intensely happy." It was a turning-point in her career, for she came to feel there that her life was at last her own, and the time for indecision and yielding was past. There were still difficulties and doubts at home, but she was no longer restless, but assured. February of 1853 saw her established at the *Sœurs de la Providence* in Paris for another short period of study, and in July of that year she took her first

attained only through difficult stumbling. "Let those," says Sir Edward Cook, "who reproach themselves for a desultoriness, seemingly incurable, take heart again from the example of Florence Nightingale! No self-reproach recurs more often in her private outpourings at this time, than that of irregularity and even sloth. She found it difficult to rise early in the morning; she prayed and wrestled to be delivered from desultory thoughts, from idle dreaming, from scrappiness in unselfish work. She wrestled, and she won." To her again the palm of victory!

Again, the unfulfilled longing that so long possessed her for practical expression of her powers and mission, and her habits of self-examination and of religious thought, did not prevent her from sharing in a very full way the life that went on about her. Florence Nightingale was no sad-eyed ascetic. We hear of her managing private theatricals, mothering young cousins, nursing maiden aunts, absorbed in housekeeping responsibilities, sympathizing with the love affairs of friends, and a host of other things. No happiness could exceed that of that winter in Rome.

Nor did she escape that experience that comes to almost every man and woman in life. She was sought in marriage, long and persistently, by one with whom her own heart was engaged. With a clear-sightedness, born of her consecration to an ideal stronger and higher than for self, she put this form of earthly happiness behind her, feeling that she could not do her duty to him and to her work. Not from any belittlement of the married state, nor from any lack of knowledge of what the higher kind of marriage might mean to them both did she act, but in the same spirit that prompted Saint Theresa or Santa Filomena. One of the most touching of her good-bye letters before she left for the Crimea was from this friend. "You undertake this," he wrote, "when you cannot undertake me!"

(T. B. C.)

post, as superintendent of the "Sick Governesses Home" on Harley Street. Here she remained, winning the confidence of a difficult committee, and a still more difficult class of patients, until a short time after the outbreak of the Crimean War.

In this little sketch of Florence Nightingale, during her time of aspiration and probation, there are many aspects that have not been touched upon at all. Her character was indeed fair and pure, as these early portraits well show, but there were shadows as well as lights within it. The requirement, for instance, of the remarkable habits of precision, regularity and method that characterized her later years was

### THE PRESENT STATUS OF ALVEOLAR OSTEO-MYELITIS (PYORRHEA ALVEOLARIS). ITS CAUSES AND TREATMENT WITH VACCINES.\*

By LEON S. MIDLAR, M.D., BOSTON.

#### INTRODUCTION.

It is now almost ten years since I first began the use of vaccines in various diseases due to bacterial infections, among which was the

\*Read before the Boston Society for the Study of Bacteriology, April 15, 1914.

ease known as "pyorrhea alveolaris," but which is in reality an alveolar osteomyelitis. The vaccine treatment of this disease had found such favor among the dental profession to the extent that I was able to report 115 cases in 1912 before the National Dental Association in Washington. Anyone interested will find in that article, published in the *BOSTON MEDICAL AND SURGICAL JOURNAL* (Dec. 19 and 26, 1912), a detailed description of the cases treated, with a complete account of the bacteriological findings, urine and feces examinations, as well as of the local and systemic conditions found in each patient. I have had under observation since then 82 additional cases which will be reported in detail later.

What I wish to take up in this paper, however, more especially, is the present status of this disease, paying special attention to the new claims made by various workers in this field as to its causation and treatment. I shall take great pains to separate the wheat from the chaff, and discuss, in as concise a way as possible, my impressions of the latest developments in this most intractable and important of mouth infections.

#### ETIOLOGY.

The thorough understanding of the anatomical relations between the alveolar process, socket and root of the tooth is absolutely necessary before any one can have a proper conception of the cause of this disease, of its prognosis and of its treatment. In the paper<sup>1</sup> presented before the National Dental Society already referred to, I have called attention to the true anatomical relation between these structures. I have emphasized again the importance of this same thing in another paper read before the Merrimack Valley Dental Association.<sup>2</sup> It seems, however, from recent literature on the subject, that this fundamental knowledge of the anatomical and physiological relations of the alveolar process, socket and root of the tooth has not as yet percolated to those who seem to be interested in this subject. They still cling to the erroneous impression that there is a periodontal membrane which acts as a sort of cushion to the tooth. They also refer to this as a "periosteum which is continuous with that of the surface of the jaw bone, but it also continues up and covers the neck of the tooth." "Pyorrhea dentalis and alveolaris," they say, "affects primarily the dental and alveolar periosteum."<sup>3</sup> The fact is that there is no such thing as a "dental periosteum."

I feel that if it were not for this misunderstanding of the anatomical and physiological relations of these parts, the dental and medical literature would have been saved a great deal of wild and baseless statements in relation to the etiology and treatment of this disease. I feel it incumbent again to emphasize the true anatomical relation which the tissues surrounding

the root of the tooth bear to its socket, and what the alveolar process really is.

The alveolar process is nothing more than the thinned-out edges of the maxillary bones and their trabeculae or bony offshoots, as has been well demonstrated by Malassez,<sup>4</sup> and is not a bone distinct from the maxilla, but is *part of* the maxilla. The socket is nothing more than an enlarged medullary space of the maxilla, and is made up of the above-described bony offshoots which constitute the alveolar process, while instead of the so-called "periodontal membrane" or the "dental and alveolar periosteum,"<sup>73</sup> we really have an alveolo-dental ligament,—bundles of *ligament* fibers which run from the wall of the bony offshoots of the alveolar process and maxillary bone and are imbedded deeply into the cementum of the root, forming a circular ligament which keeps the tooth suspended in the alveolar cavity. Between these bundles of ligament fibers there are spaces filled with loose cellular tissue—medullary spaces—which communicate with other similar medullary spaces of the maxilla and alveolar process. These spaces contain the voluminous blood vessels and nerves of that region. (In a recent book on Dental Pathology, by Black,<sup>5</sup> as well as that by Kirk,<sup>6</sup> we find some mention made of fibers as being present in the periodontal membrane. But they do not refer to them as *ligament* fibers. The mere description of the finding of fibers histologically does not convey any special meaning as to what these fibers really are, and one could never learn from those descriptions that they refer to *ligament fibers*, and that the tooth is held by a circular ligament attached to the maxillary bone.)

The nature of the disease under discussion, as has been well demonstrated by Znamensky,<sup>7</sup> is a downward process. It begins with an inflammatory process of the gum margin, soon involves the medullary spaces of the alveolo-dental ligament and the alveolar process—the bony offshoots themselves—which becomes necrotic and is in time dissolved away. The disease finally involves the marrow spaces of the maxillary bone itself. We can, therefore, only refer to this disease under the circumstances as an osteomyelitis of the alveolar process and maxillary bone. It being a chronic condition, as a rule, we have, I believe, no choice but to consider it as a *chronic alveolar osteomyelitis*.

So-called "pockets without pus," referred to by dentists as "dry pyorrhea," I have always found to contain pus and bacteria, and occasionally endameba on microscopic examination, showing a definite infection with a suppurating process, which has begun on the surface and has worked downward, and not vice versa, as one would infer, if the disease were due to endameba.

Having described the true nature of the anatomical relation of the alveolar process, socket and root of the tooth, without which I feel no

dentist could see light upon the subject, we can now pay attention to the specific causes, if any such there be, of this disease.

#### ENDAMEBA BUCCALIS.

Owing to the prominence given in the medical and dental literature to the claims made by Bass and Johns<sup>8</sup> for this harmless unicellular organism—the endameba buccalis—as being the “specific” cause for pyorrhea, we shall have to look into these claims to try, if we can, to establish how much truth, if any, there is in them.

As far as I can see, the principal underlying reasons given by Bass and Johns<sup>8</sup> for these claims are: (1) the fact that the endameba is present in greatest numbers in the deeper parts of the pockets and to a lesser degree in the upper parts of the pockets; (2) the erroneous claim made by them that this organism is not found in healthy gums; and (3) the fact that emetin, a well-known amebicide, when administered to patients suffering with this disease, was followed by an improvement in the condition, and caused these amebae to disappear.

As to the first contention, the fact that it is found in the deeper parts of the pockets is referred to by them as chief evidence for its being the “specific” cause and they say, “What more evidence of pathogenicity do we need?” As if the mere finding of any harmless organism, demonstrated by various observers to be harmless, would be sufficient to establish the claim for such organism as being the “specific” cause of a disease. They pay no attention whatsoever to the presence of bacteria, known to be pathogenic, present in great abundance in these deeper parts of the pockets, and upon which these endamebae really feed and are rather of help to the patient, as has been stated by Chiavaro.<sup>9</sup>

Their second claim, that endamebae are not found in the gums of healthy individuals, has been refuted by Lewald,<sup>10</sup> who described this endameba over seven years previous to Barrett and Smith's<sup>8</sup> and Bass and Johns' description of this organism. Lewald was able to convince himself from his studies “that these amebae could be demonstrated in the month almost constantly, no matter how much care was taken of the teeth.” He “examined persons coming from all parts of the country and abroad, and the constancy with which the organisms had been found left no doubt in his mind as to its presence in the human mouth in health, equalling in this respect the presence of the *B. Coli* in the intestines.”

A very careful piece of work on the subject was reported by Angelo Chiavaro,<sup>9</sup> who concluded from his researches that the endameba “is generally present in *materia alba* of the sound teeth if they are not kept in a good hygienic condition.” And finally that the “endameba has not a pathogenic action. On the contrary, as it feeds on bacteria, it is most probably an aid to the auto-disinfection of the mouth.”

Anna Williams and her co-workers<sup>11</sup> of the Research Laboratories of the New York Board of Health have found this endameba in 30% of children with healthy gums, in 50% of children with healthy gums and carious teeth, in 84% of children showing tartar around teeth and receding gums, and in 94% of children with spongy gums.

Finally, Price and LaRue<sup>12</sup> in their summary on this subject, prepared for the Scientific Foundation and Research Commission of the National Dental Association, stated that they have been unable to find the endameba in severe pyorrhea cases, and that in many cases the use of emetin has given poor or no results. They state that the proof is as yet insufficient that the endameba has anything whatever to do with the production of pyorrhea.

I have personally examined several cases of alveolar osteomyelitis (pyorrhea) with results similar to those of Price and LaRue. In some of the most severe cases, with considerable pus, I could not demonstrate this organism after a prolonged search of several stained slides; while on the other hand, they were quite fairly abundant in patients who have taken several bottles (6 bottles in one case) of alcresta pills (40 tablets, I believe, to the bottle), without showing any improvement in the condition, and who have, therefore, applied for vaccine treatment.

I cannot help but sum up that the evidence is very much against the Endameba Gingivalis (*Buccalis*) having any causal relation, and especially a “specific” etiologic relation to alveolar osteomyelitis or “pyorrhea.”

Their other claim, that the use of emetin has been found by them to cause the disappearance of the ameba in the pockets and an improvement of the condition locally,—as being another indication that the ameba is the cause of this disease,—can be refuted by the fact that whatever improvement was noticed in this disease from its use could be easily ascribed to the hemostatic action of the emetin and its antiseptic (bactericidal) effect. Numerous cases, however, are appearing today where there has been neither disappearance of the endameba by the use of the emetin nor the improvement of the disease, so this last fundamental claim for the endameba as the “specific cause” of alveolar osteomyelitis falls to the ground.

In fact, we find in small type under the heading “Note,” in the book by Bass and Johns,<sup>8</sup> this statement: “Since our early publications we have seen a considerable number of cases in which endamebae have reappeared after they had been absent for various periods of time following the use of emetin in one way or another. . . . We have also seen . . . they saw a considerable number of cases in which the endamebae have not been eradicated even after short time, by emetin.”

This admission, though in very fine type, of

the failure of emetin to have even an effect upon the endamebae, without mentioning the failures in improving the condition by this treatment,—all of which has been admitted by the very men who claim for the endameba the "specific cause" in connection with this disease,—is in itself sufficient to refute their own claim.

Personally, I feel that owing to the anatomical relations of the tissues surrounding the root of the tooth and the disease in question being really pathologically an osteomyelitis, no one organism can possibly be found to be the specific and only cause of this disease, any more than it can be said that any particular one bacterium or protozoön can be the only specific cause of an osteomyelitis affecting any other bone of the body. The more I have to deal with this affection, the more am I convinced of the truthfulness of my statement made before the National Dental Association in 1912,<sup>1</sup> to the effect that "chronic alveolar osteomyelitis is not due to a specific microorganism present in all cases, in the same way as tuberculosis is always caused by the tubercle bacillus, but is due, according to my own findings, and those of other investigators, to a mixed infection of different bacteria, the most prevalent being the strepto-pneumococcus variety."

#### BACTERIA IN ALVEOLAR OSTEOMYELITIS.

I have already described in detail, in the paper presented before the National Dental Society in 1912, the relation of bacteria to this disease. The large number of investigators on the subject, beginning with Galippe<sup>14</sup> as far back as 1888, Miller<sup>15</sup> in 1890, Kirk,<sup>16</sup> Black,<sup>17</sup> Von Arkövy,<sup>18</sup> Goadby,<sup>19</sup> Ayre and Paine,<sup>20</sup> and the host of other investigators have described one or more forms of bacteria of the suppurating types in connection with this disease, the predominating one being that of the strepto-pneumococcus variety.

In the 112 cases I have already reported where cultures were obtained, 107 had this strepto-pneumococcus type of organism, either alone or in conjunction with one or more other bacteria. In the 82 additional cases I have had to date the bacteriological findings were practically the same as those described. A number of observers prefer to call this organism streptococcus viridans. I have considered it pneumococcus in chains, or strepto-pneumococcus. These bacteria are known to be pus-producing bacteria and, when inoculated into animals, produce disease and suppurative changes. I have personally been able to produce (as already reported<sup>1</sup>) inflammatory changes in the gums of dogs with the bacteria isolated from "pyorrheal" pus, changes sufficient to prove the pathogenicity of these organisms and their relation to alveolar osteomyelitis.

The relation of these bacteria to alveolar osteomyelitis is further demonstrated by the fact

that patients suffering with this disease have yielded to the autogenous vaccines made from these organisms and administered to them. The response to the vaccines being specific, the vaccines could, therefore, have no other effect upon the disease unless it be to immunize the patients against the infectious agents (bacteria), to which we attribute the cause of this disease, and from which the autogenous vaccines are made.

Probably as important a fact in favor of the bacterial cause of this disease is the systemic diseases secondary to this local alveolar osteomyelitis.

A great deal of work has been done on the systemic secondary infections, important among which is that of Rosenow,<sup>21</sup> who demonstrated the strepto-pneumococcus type of organisms in the joints and muscles of patients suffering with rheumatism, apparently secondary to the alveolar infections. I believe that the mode of spread of infection from the oral cavity is principally by way of the blood,—the bacteria invading the blood either directly from the local focus of infection or from the stomach and intestinal tract, as has been found at the Pasteur Institute.<sup>22</sup> Antitoxin, if obtained from a horse after a meal, was found at the Pasteur Institute to develop microbes, no matter how carefully it was obtained. The horse, therefore, is bled after he is kept fasting, in order to obtain a sterile serum (antitoxin). Such microbe invasion of the blood from the intestinal tract is always to be kept in mind. The only protection against it, it seems to me, in the disease under discussion, next to eradication of the local foci, which may not always be possible, would be by raising the blood resistance by means of autogenous vaccines to such organisms as might be swallowed with the "pyorrheal" pus.

Since it is unanimously admitted that the secondary infections—secondary to the local mouth infections—are of bacterial origin, I can see no rationality in the paradoxical claim made that the original local foci of infection are not of the same bacterial origin. (So much for the bacterial cause of the disease.)

It may be worth while to say a few words in connection with Talbot's theories as to the causation of alveolar "pockets." Talbot<sup>23</sup> describes them in answer to the question that he asks himself, "What are pockets?" thus: "They are spaces," he says, "between the gum and the root of the tooth, due to irregular absorption of the alveolar process." "Halisteresis [lime absorption] or perforating canal absorption," he says, "is the most common in the disappearance of the alveolar process. . . . This, together with the destruction of the periodontal membrane in this area, is what would be called a pocket."

Talbot has apparently described the findings of the condition as they appear microscopically, but he has given no cause for the production of

such pockets. He is, besides, very much put out by the suggestion of the "germ theory" as having anything to do with the causation of disease in general and the production of alveolar osteomyelitis (pyorrhea) in particular.

He also says, "A pus infection is always a secondary matter, since the pockets are there, whether the pus is present or not." As a matter of fact, by obtaining material from such so-called dry pockets with a platinum loop or with a fine probe, I have personally always found on microscopic examination of such material considerable pus and bacteria present. Talbot, as well as a great many others in the dental profession, overlooks the possibility on the part of bacteria to produce toxic substances capable of causing the death of the tissue cells, which dead tissue nature will try to get rid of by gradually dissolving it, whether it be soft tissue or bone, thus causing a pocket in the alveolar process similar to the sinus or fistulous infection in any other tissue or bone.

Bacteria of whatever type, then, capable of implanting themselves and causing infection, will elaborate toxins, which in turn give rise to death of tissue cells. The dead tissue gradually dissolves away and discharges, forming a "pocket." The ability on the part of the bacteria to cause infection will depend upon the high virulence of the bacteria, also upon the general lowered resistance of the individual or upon the lowered resistance of the tissues locally, due to local irritation produced by tartar deposits, mal-occlusion, ill-fitting crowns, and a number of other local irritants.

I have discussed and touched upon the etiology of this disease, bringing the subject, I believe, up to date. We shall now take up the treatment of this condition, and I shall try again to call attention to the important points in the treatment which have a definite bearing upon the etiology of this disease.

#### TREATMENT.

**Instrumentation.** I shall not go into the details as to the use of instrumentation in this disease, since I have always depended upon the dentist for this phase of the treatment. The principles of instrumentation, however, as far as I can see, which should be kept in mind by every one, are: the removal of local irritation, such as tartar deposits and calculi when present; avoiding ill-fitting crowns and injurious plates; doing away with mal-occlusion; removing all teeth that cause crowding of other teeth; keeping pockets open so they can readily drain; and, with the aid of the X-ray, to determine which of the teeth have lost all their bony support, which teeth should be removed.

It is interesting in this connection to cite Merritt's<sup>24</sup> view "that pyorrhea can be prevented in 90 to 100%" and that it "can be cured by instrumentation, provided only that it is done skilfully." While Talbot<sup>25</sup> says: "In

the treatment of pus pockets, the less instrumentation used to remove the deposits upon the roots of the teeth, the better. All that is necessary is to give nature a chance."

Here are the views of two extremists on instrumentation. One thinks he can cure by instrumentation alone practically all cases of alveolar osteomyelitis, throwing down everything else suggested in connection with the treatment of this disease; while the other would not even have you properly remove the deposits on the roots of the teeth. The truth of the matter is that some dentists go much too far with instrumentation, while others do far too little. The happy medium is what is required.

The proper knowledge of the anatomical relation of the root of the tooth to its surrounding tissues, the thorough understanding of the principles underlying instrumentation, together with the proper conception of its limitations, will all help one strike the happy medium in this phase of the treatment.

#### EMETIN TREATMENT.

I can say at this present time for emetin treatment that the consensus of opinion is that whatever improvement has been noticed from its use is not so much due to its effect upon the endameba, but rather to its hemostatic action, as well as its bactericidal properties. It is surely not a curative agent because of the nature of chemical drugs in general and their effect upon chronic diseases. No sooner do you stop their use than they immediately are eliminated by the system, allowing the infectious agents, of whatever kind there may be, at once to start the process up again. As already quoted from the book by Bass and Johns, the original advocates of this treatment, they have found a considerable number of cases in which the endamebae have reappeared after they had been absent for various periods of time following the use of emetin, in various ways, and again a considerable number of cases where the endamebae have not been eradicated for even a short time by emetin. They have, therefore, been advising recently the continuous use of this drug in patients suffering with this disease. Reports are coming in thick and fast now, both in the medical and in the dental literature, of the failure of emetin in this disease from men who have used emetin in a large number of cases, and have found it of very little help. Even in the most optimistic report on the use of emetin, presented by Rudolph C. Lineau,<sup>26</sup> where he claims that the inflammatory condition in the mouth subsided after the injection of emetin, he, too, believes that the improvement was due to the hemostatic action of the emetin, and not to its specific effect upon the endamebae.

A very good article on the endamebae of the mouth was published by Charles F. Craig, who had treated several "pyorrhea" cases with emetin "in the most approved way for several

weeks." He has found: whereas the endamebae generally decreased in number by its administration, they certainly were not eradicated, and that a similar decrease in number was true of the spirochetes. There is just as much ground to consider the spirochetes as the cause of the disease because of their presence before, and the decrease after the administration of this drug, according to him, as there is to consider the endameba to be the "specific" cause of pyorrhea.

It is rather surprising to read in an article in this connection, by Kolmer and Smith,<sup>27</sup> that they have studied the bactericidal action of emetin in vivo on staphylococcus aureus, bacillus tetani and bacillus anthracis, all of which organisms are not at all related to the disease in question (with the rare exception of the staphylococcus aureus, perhaps). Their findings have, in my opinion, no bearing upon the controversy and will help very little to establish the effect of the emetin upon the bacteria found in the pockets of this disease. They certainly have no ground under the circumstances to say in conclusion: "Improvement or cure of this disease with subcutaneous injections of emetin is to be attributed solely to its amebicidal action," though they concede some coincidental bactericidal influences on the part of the drug when used locally in the pockets.

I do not mean to minimize the amebicidal action of emetin. This has nothing to do with its bactericidal effect and hemostatic action, which alone are sufficient to account for whatever slight improvement in the gum is noticed in this condition under its use. Personally, I have had no occasion to use emetin, since the autogenous vaccines have given me the desired results. However, cases have come to me applying for vaccine treatment upon whom the emetin treatment had already been tried and had failed, and I have had, as it happened, five such cases in one week recently. I found in these cases where, possibly, according to the statement of the patient, there has been slight diminution in the *visible* pus, some improvement in the inflammatory condition and bleeding, yet the loose teeth were still loose, as before, and the pockets still contained pus, bacteria, and, in some, quite a few endamebae, as shown upon microscopic examination of slides made from such pockets. Their applying for vaccine treatment is sufficient evidence of the failure of emetin in this disease.

#### MERCURY SUCCEINAMIDE.

Mercury succinamide is another drug for which considerable claim has been made by B. L. Wright,<sup>28</sup> in the cure of this disease. Wright has gone so far as to claim 100% of "cures" with it. The extravagance of such claim in itself is almost sufficient to make one pay little attention to it.

The cases treated by Wright and his co-work-

ers, as far as I can make out, were mostly men who had probably paid little attention to the proper hygiene of their teeth and gums; if such men receive a thorough cleansing by a dentist, tartar deposits being removed, and the cause of inflammatory irritation done away with, their gums respond in the most miraculous way, as we all know. And in what would seem to some a hopeless case of alveolar osteomyelitis, no other treatment but a good cleansing by a dentist and attention to the general hygiene of the mouth, as described, would cause the gums to show such striking improvement in a short time as to make the unwary believe that he has had 100% of "cures."

It is totally different in cases of private practice among the better class of patients, where the teeth have always been attended to by dentists, and the mouth and gums kept in the most hygienic way by the patient. In such cases, when we get this disease, the mere inoculation of mercury, I do not believe, will have more than a passing effect, if any at all, and the use of antiseptics or antiparasitics alone will, I believe, be found very much of a disappointment.

Nothing would have pleased me more than to find that such simple means as the injection of emetin or the taking of aleresta tablets by mouth, or even the less simple and more painful remedy of the deep intramuscular inoculation of mercury, would yield the proper results in this important mouth infection, since the experience I had with this disease, and because the way in which I found results, has been a much longer road and a much more difficult one to travel,—one that requires painstaking attention to details and bacteriological methods of the highest order.

#### VACCINE TREATMENT.

This treatment has been such that it has proven in my hands to give more satisfactory results in this disease than any other treatment as yet suggested. It has withstood the hardest test—time. The good results I have obtained with it have not been a question of a few weeks or a few months' experience, but it has been a matter of over nine years' work.

*Method of Procedure.* In my own practice, cases with alveolar osteomyelitis, who apply for treatment, are given a thorough physical examination. The history is carefully taken, and particular attention paid to any special cause or causes that have been noticed by the patient to have given rise to a sudden exacerbation of the gum trouble at any time. A careful urine analysis is made, examination of feces, both chemical and bacteriological, is done. Blood is examined microscopically. Wassermann test for syphilis is done in all cases that are at all suspected of the disease. Cultures from the gums, pockets, nose and throat are obtained, and a thorough bacteriological examination made. Autogenous vaccines are prepared from such

sources that appear at all suspicious of causing infection. (For technic of cultures see note.\*) The details of the laboratory findings, both chemical and bacteriological, can be found by anyone interested, in my paper already mentioned.<sup>1</sup>

The following table (Table A) is the summary of the bacteriological findings in the 115 cases reported.

The chemical examination of the fees reveals the presence of an excessive amount of undigested meat or starch, and by means of Schmidt's fermentation test it is possible to detect whether the particular intestinal fermentation, of which the patients complain, is that of the carbohydrate fermentation or meat putrefaction. This chemical examination was found of the utmost value in deciding upon the proper diet for the individual case. The urine analysis would, of course, give a clue as to whether the patient is suffering from any kidney disease or diabetes.

The discovery of such disturbances of systemic conditions is, I believe, of the utmost importance for the successful treatment of the disease in question.

**Vaccine Treatment.** This treatment is in reality an artificial active immunization of the individual against such bacteria as are used in the form of vaccines; so that when we obtain bacteria from the alveolar pockets that are causing the infection, and make an *autogenous* vaccine in each individual case, the patient receiving such autogenous vaccine is in reality being immunized against the particular bacteria which are causing the infections of the gum and the alveolar process. This is the only direct way, we know of, to raise the resistance of the individual against such bacterial infection. The vaccine is not a serum or a lymph obtained from an animal, and it is not in any way an

\* **Technic:** Cultures from the gums were obtained in the following manner. The lips or buccal parts were kept away from the affected tooth by means of a sterile tongue-depressor by the patient or assistant. The gums around the affected tooth were carefully wiped off with sterile cotton. The pus was then squeezed out by means of a sterile swab. This pus in turn was collected with a fresh swab and labeled No. 1. Further pressure would cause a second and third drop to ooze out which were collected on a second and third swab respectively. The first drop of pus was smeared upon cover slips for the direct microscopic examination while the second and third drops of pus were used for cultural purposes. In cases where there was no visible pus present (timpant and some moderately-advanced cases) the gums showing the most sluggish inflammation or recession were used. A sterile heavy platinum wire was used to obtain material for cultural purposes, alongside of swabs, from the "pocket," if any were present. Several culture tubes were inoculated at the same time and results compared. All efforts were made in each individual case to obtain cultures from the pus or affected places, as free from contaminating material or contaminating organisms as is possible under the strict bacteriological methods.

† Pneumo., in the above table, refers to the streptopneumococcus type of organism.

animal product. It is in reality a suspension of killed bacteria, suspended in sterile salt solution containing a quarter of one per cent. of phenol.

**Autogenous versus Stock Vaccines.** The autogenous vaccine is, of course, a suspension of the killed bacteria obtained from the individual patient who is to be treated, while the "stock" vaccine is a mixture of organisms obtained from others than the individual patient, so that in treating patients with "stock" vaccines, the production of antibodies being specific, the results would, of course, be indifferent, since the bacteria of which "stock" vaccines are made up, although they may resemble microscopically and culturally those obtained from the individual patient, still may have, and usually do have, different individual biologic characteristics. Practically all the cases I have personally had under observation have been treated with autogenous vaccines, at times in combination with the corresponding stock vaccines; the latter, in order to raise the resistance of the patient to infections which he might pick up, even after his resistance to his own individual bacteria has been raised.

**Administration of Vaccine.** The vaccine is administered in the upper arm, and if a fine needle is used (gauge 26) there is very little feeling of pain attached to the inoculation. If the proper amount of vaccine is used, there is very little after-effect from it. The most that can happen is slight redness and slight soreness around the focus of injection, lasting for 12 to 24 hours. No general reaction ever occurs if the proper dose is given.

The actual results obtained in the 115 cases I have reported in 1912, treated with vaccines, are shown in Table B.

TABLE B.

Stage.	No. of Cases.		Periods.		Results.	
	Cured.	Improved.	No Improvement.	Cured.	Improved.	No Improvement.

Far advanced 37	40	4	43	47	5	—

The results in the 82 cases I have had since have practically been the same, though I have had no opportunity as yet to tabulate them.

## GENERAL SUMMARY.

In summarizing briefly the subject under discussion, I would say that the alveolar process, so called, surrounding the root of the tooth, is simply the thinned out edges of the maxillary bone, while the socket is nothing more than an enlarged medullary space of the maxilla. The "peridental membrane" so called, is really made up of bundles of *Epithema fibrovascularis* from the bony processes of the maxilla and

inserted into the root of the tooth. They are arranged in a circular form, making a circular ligament, but it is a *ligament*, and not a "membrane" nor a "periosteum." (Any one could satisfy himself to that effect when he thinks how the acrobat can develop the strength of his teeth so that he can hold an anvil with them, with somebody hammering on it.) In between these bundles of ligament fibers we have spaces which connect with the medullary spaces of the maxillary bones, and are filled with loose medullary cells, that hold the nerves and blood vessels of the part.

The disease begins with a local irritation at the gum margin, causing a lowering of the resistance of the tissues locally, thus allowing the bacteria to implant themselves, reproduce and cause infection. If the irritation is not at once removed, it is obvious that such infection, though mild in the beginning, would spread farther down towards the bone itself, causing congestion and sponginess of the gum, and finally attacking and dissolving the alveolar process itself, forming fistulous sinuses or pockets, and if allowed to go on it finally destroys the whole of the bony socket and the tooth is loosened up. So much for the progress of the disease and its formation.

Now, with reference to the endamebae and their relation to alveolar osteomyelitis, there seems to be very little evidence at the present time for the recent claims made, that the endameba buccalis is the "specific" cause of this disease. Even if it had any pathogenic properties, which is very much doubted by very good authorities on this subject, there is no real ground to attribute to it the "specific" cause of this disease.

Whatever improvement has been noticed by the use of emetin in this disease could easily be explained by the increased attention given the patient by the dentist, by the hemostatic effect and the bactericidal or antiseptic action of the emetin. In those cases where the pockets have been actually washed out with the emetin solution, the improvement, I believe, is due under those circumstances to the local washing out of the pockets by improving their drainage, and to whatever antiseptic value the emetin has, if not wholly to that, rather than to its amebicidal action; so that in the ameba we have neither the specific cause of the disease, nor in the emetin its "cure."

As to the deep injections of mercury in this disease, I feel that where improvement did follow its administration, it was due to the fact that some of the patients were probably primarily suffering from syphilis, while the vast majority of the cases treated by the men who claim that they can obtain 100% of "cures" with it, has been probably in patients with very neglected mouths, where the gums have been aching for attention rather than for mercury. The pain produced by the deep intramuscular in-

jections of mercury should always be kept in mind, even when treating syphilitic patients, and for that reason the internal use of the various iodids of mercury, or mercury with chalk alongside of the salvarsan treatment, is to be preferred. Finally, the deep intramuscular injection of mercury will, I believe, be found of no more value in the treatment of this disease than its use in pulmonary tuberculosis, for which as much has been claimed by the same advocate of the mercury treatment. In the latter disease, as far as I know, mercury succinamide has been faithfully tried, and failed, in the hands of various men throughout the country.

*Relation of Bacteria to This Disease.* The bacterial relation in this disease has been demonstrated by means of the bacteriological findings of smears and cultures, by the secondary systemic infections and by the response of the disease to the autogenous vaccine, and, finally, by actual animal inoculation and the artificial production of inflammatory changes in the gums of dogs. Although the inflammatory changes produced in the gums of dogs used were not lasting (possibly due to the good general condition of the dogs I have used for the experiments, and the lack of local mechanical irritation), still it was sufficient to show that the organisms (strepto-pneumococcus) isolated from the alveolar disease do cause inflammatory changes if artificially inoculated into the gums of animals. It is true that there may be a difference of opinion as to the nomenclature of this organism, some calling it streptococcus viridans, others, pneumococcus or strepto-pneumococcus. The organism, however, remains the same by whatever name it is called. Personally, owing to its close relationship to the pneumococcus, I considered it strepto-pneumococcus. However, even with the bacterial relation of such organism to this disease being established, it is far from my mind to consider it as the "specific" primary cause of alveolar osteomyelitis. This disease really has local mechanical irritation, local bacteria, systemic general lowered resistance and systemic diseases as causes; and if one is to hope at all for any cure in this disease, one must attack them all.

I can do no better in concluding than to repeat the "conclusions" I have arrived at in 1912<sup>1</sup> on this subject, and any one who can read, and think while reading these conclusions, will find practically everything that can be said on the subject, in a few words.

#### "CONCLUSIONS."

1. "Pyorrhea alveolaris," so called, is in reality a *chronic alveolar osteomyelitis*. It should be known and treated as such.

2. The sockets are enlarged medullary spaces of the maxillary bones while the so-called "periodontal membrane" is in reality a *ligament* which keeps the tooth suspended in the alveolar cavity.

3. The mechanical causes are responsible for starting the disease, while the pyogenic bacteria (pneumococcus, staphylococcus, and *M. catarrhalis*) are responsible for keeping it up.

4. Chronic alveolar osteomyelitis is a specific disease, though not in the sense that it is always due to one and the same organism; it is due to a variety of organisms, already enumerated.

5. Systemic diseases play only a secondary part in starting the disease, but may be caused by it, and in turn become responsible for keeping up the local condition.

6. A great many rheumatic diseases, so called, also a great many gastro-intestinal affections are, in my opinion, directly related to chronic alveolar osteomyelitis—"Riggs' disease."

7. The vaccine treatment of this disease, together with the proper attention to diet, cures or relieves the systemic diseases, especially the rheumatic affections.

8. Vaccine treatment (immuno-therapy), together with local mechanical treatment (and the proper attention to the general systemic condition of the patient) yields by far the best results in this intractable disease—*chronic alveolar osteomyelitis*.

## THE USE OF EMETIN.\*

By ALFRED C. REED, M.D., SAN FRANCISCO.

*Clinical Instructor in Medicine, Stanford University School of Medicine, San Francisco.*

EMETIN can be estimated today as one of the major drugs, particularly in medical practice in hot climates. A better understanding of its activity, as well as of its limitations, together with recent extensions of its field of usefulness, makes it an important drug also for medical practice in temperate climates. The tremendous destructiveness and menace of amebic dysentery has been removed by its introduction, and it has been employed in pyorrhea with at least helpful results. It has also been used in certain non-amebic conditions, where its results are open for interpretation.

The literature on emetin is so extensive and there are so many conflicting opinions regarding it, that it is not feasible at this time to enter into a detailed discussion. It is the intention of this paper rather to present in more or less didactic form the salient features of the history, pharmacology, toxicology and use of emetin, all of which must necessarily be brief, and rather an outline than a connected thesis. It is hoped, too, that such an outline will arouse practical discussion of the points presented, especially in their clinical bearing.

## HISTORY.

According to an editorial writer in the *British Medical Journal* (Nov. 13, 1915), ipecac was introduced into Europe from Brazil, where it had been used for an indefinite period, in 1648, by G. Piso, who was a companion of the Duke of Nassau in his explorations in Brazil and the West Indies. No further notice, apparently, was taken of the drug until the exploitation of a secret remedy for dysentery by J. A. Helvetius, in Paris, in 1686. This physician successfully treated the Dauphin, the son of Louis XIV., and the preparation was then used at the Hotel Dieu, and finally the formula was bought by the French government and made public two years later. The treatment again lapsed into desuetude until early in the nineteenth century, when English physicians, especially in the army, took up the use of large doses of ipecac in dysentery. The matter was particularly forwarded by officers of the Indian Medical Service.

A mixture of ipecac alkaloids was isolated in 1817 by Paderlet and by E. Gueneau de Mussy, the name later being retained for a single alkaloid. Later on, Walsby and Porter, in 1860, obtained results in acute dysentery by the use of one grain daily of a mixture of 0.2 A. of emetin, and stated that the alkaloid was more effective and suggested the preparation of a tablet containing

for human amebiasis. Leonard Rogers in Calcutta thereupon administered emetin hypodermically in amebic dysentery and achieved remarkable results which have since been abundantly confirmed.

The history of emetin thus originates in the history of ipecac root. Then came the isolation of an alkaloidal mixture from the root and more recently the various ipecac alkaloids have been isolated and studied individually. However, not until within a comparatively few months has pure emetin been prepared. Practically all of the emetin used and even now available is impure and has been shown to have a dangerous variation in activity and toxicity. In spite of peculiar technical difficulties, refined methods of analysis have now produced a pure emetin which so far has not been thoroughly studied in either the clinic or the laboratory.

#### PHARMACOLOGY.

Hesse has devised a method of isolation which gives pure emetin. Just as Paul and Cowley in 1893 had shown that the earlier emetin was a mixture of emetin—as we now understand it—and cephaelin, so Hesse has again shown the emetin of ordinary use to contain an admixture of a cephaelin-like body. He considers that ipecac, both cultivated and wild, contains five alkaloids (Liebig's *Annalen der Chemie*, 1914, 405, 1), the most important of which are emetin and cephaelin.

Emetin  $C_{30}H_{40}N_2O_5$   
 Psychotrin— $C_{28}H_{36}N_2O_4 + 2H$  gives Cephaelin  $C_{28}H_{38}N_2O_4$   
 Ipecamin— $C_{28}H_{36}N_2O_4 + 2H$  gives Hydro-  
 ipecamin  $C_{28}H_{38}N_2O_4$

Hesse goes on to say that emetin has no emetic properties and that only contamination with other alkaloids makes it emetic. Cephaelin is the type of the two pairs of alkaloids noted, and with emetin is the most important principle in ipecac. He finds that emetin hydrobromide is considerably easier to purify than the hydrochloride. Especially is emetin hydrochloride hard to separate from ipecamin hydrochloride. He, therefore, recommends emetin hydrobromide as the preparation of choice. Against its clinical use, however, is its difficult solubility. He lays the chief danger in emetin to contamination with the strongly toxic cephaelin.

Carr and Pyman (*Journal of the Chemical Society*, 1914, 1591) arrive at a slightly different formula for emetin, making it  $C_{29}H_{40}N_2O_4$ . They state that psychotrin plus  $2H$  gives cephaelin and cephaelin plus  $CH_2$  gives emetin. Emetin can be prepared from cephaelin by methylation and this process gives a substance identical with native emetin. Emetin is a levorotatory base which yields dextro-rotatory salts. It can be prepared as a colorless white amorphous powder, or as a clear varnish. It has the general solubilities and properties of alkaloids, being soluble in alcohol, ether and chloroform,

and but sparingly soluble in water. Emetin hydrochloride, which is the salt chiefly used because of its solubility in water, crystallizes in colorless woolly needles or in thicker transparent prisms. It has no sharp melting-point. It is slowly soluble in cold water, forming a saturated solution of about 13% at 18 degrees Centigrade. It is the most soluble of all the emetin salts.

There is practically no literature so far available on the action of emetin as obtained in pure form by the Hesse method. All data are on the purest emetin to be had at the time commercially. This, however, has been proved by Levy and Rowntree (*Archives of Internal Medicine*, March 15, 1916) to vary in toxicity and action within comparatively wide limits according to the methods of manufacture of the various purveying firms. This is a matter of the utmost importance, and attention is urgently required to control the standardization of emetin preparations on the market. The data here presented, being the result of work on the older emetin which is now that in ordinary use, may be more or less modified by future experimentation with pure emetin. But thus far only the ordinary commercial preparations have been available.

The local action of emetin consists of a profound irritation of all contiguous tissues, which is at first inflammatory and later goes on to ulceration and necrosis. Inhalation of the powder of ipecac causes marked respiratory distress, which takes the form of the so-called "emetin asthma," with oppression in the chest and difficult breathing, from the local irritation. Irritative symptoms are likewise produced in the eyes and upper respiratory passages. If applied to the skin in an ointment, emetin causes irritation tending to pustulation. Subcutaneously also it produces a marked irritation, with pain, swelling, stiffness of the part, ulceration and sometimes necrosis.

Emetin has been shown to have a depressant action on the heart and circulation. A single moderate or large dose shows no effect, but repeated small hypodermic doses produce a serious fall of blood pressure in animals, with a small fast pulse. This is a symptom of poisoning and may not be elicited in the therapeutic use of the drug. Various observers at times have noted a peculiar cardiac irregularity which Levy and Rowntree have shown to be due to a coarse ventricular fibrillation. The fibrillation is first generalized. Then the auricle ceases to beat, becomes engorged and dilates. The heart ordinarily stops in diastole and this stoppage is synchronous with respiratory failure. This cardiac effect in animals was unaffected by cutting the vagi. In some cases the normal rhythm is resumed after a temporary period of fibrillation. Cephaelin has a more profound influence on the blood pressure than has emetin, but the latter is more toxic to the

heart itself. Death in emetin poisoning comes from cardiac failure.

On the gastro-intestinal tract emetin seems to act as a general irritant, producing vomiting and diarrhea when the dose is sufficient. Anorexia, gastric distress and headache occur. Hesse claims that pure emetin has no emetic action and that the alkaloid is therefore misnamed, its emetic properties being due to an admixture of cephaelin. But the consensus of opinion is to the effect that emetin does act as an emetic. Wild found the emetic action of cephaelin to be double that of emetin. Emesis seems to be invoked only when the alkaloid is administered by mouth, except possibly when toxic amounts are injected. The writer has seen several cases where emetin was administered in keratin coated pills and produced violent diarrhea, colic and tenesmus. The ordinary preparations certainly have a marked emetic action when given by mouth. It has not been definitely determined whether there is an interrelation between the emetic action and the effect on the circulation, particularly on the blood pressure. Emetin has an action on the respiratory tract which is most likely secondary to a mild degree of nausea.

An important addition to the knowledge of emetin action is recorded by Levy and Rowntree who report the observation of Professor Howell to the effect that the blood of emetin-poisoned animals clots with unusual slowness and that the clot is non-retractile in character, soft and of a jelly-like consistency, "showing no visible structure whatever under the ultramicroscope, whereas the normal clot shows a mass of interlacing needles or spicules." No characteristic or pronounced change is produced in renal function until the terminal stage of poisoning.

The action of emetin as an amebicide was first demonstrated by Vedder and is the basis of its employment in amebic infections. It destroys the vegetating amebae but seems not to affect cysts. So that practically the symptoms of the action of the drug are in reality by-products which are not necessary or even desirable in its therapeutic administration. The few exceptions to this will be taken up under the uses of the drugs. In considering the pharmacology of emetin even thus briefly, mention should be made of the use of chaparro amargoso, a Mexican plant, which has an action similar to ipecac and may contain similar principles.

#### TOXICOLOGY.

The symptoms of emetin poisoning are comprehended in the statement of the physiological action, as the therapeutic effect is only or rather is chiefly amebicidal. The ordinary symptoms of poisoning consist of gastro-intestinal irritation, low blood pressure with fast weak heart, general depression of the central nervous system and often a condition scarcely

to be distinguished from acute beriberi. The gastro-intestinal irritation is apt to appear quicker and to be more violent if emetin has been administered by mouth. It has been claimed that emetin stimulates the vomiting centre in the medulla, but the observation is not well substantiated, and the extreme infrequency of vomiting when emetin is administered hypodermically argues against it. However, Allen reports (*J. M. A.*, 1913, 664) a case of emetin poisoning following hypodermic injection of four grains of emetin where there was nausea and some vomiting. Diarrhea with blood, mucus and much pain and tenesmus may occur after the use of emetin hypodermically, and the mechanism of its production is not clear. The manner of excretion of emetin has not been determined. If it is excreted through the large intestine this might account for the action. But no trace of ipecac alkaloids could be recovered by Lowin from gastric or intestinal contents or from the urine. (*Arch. Internat. de pharmacol. et de Therap.*, 1902, xi, 9.) Lyons moreover was not able to show any amebicidal action of the sterilized stool filtrates from individuals who were taking ipecac by mouth. (*New Orleans M. and S. Jour.*, 1912, 881.)

It is hard to dissociate the circulatory effects of emetin from its poisonous action on the gastro-intestinal tract. The difficulty of recognizing these poisonous symptoms is greatest in the condition where above all others the use of emetin is important,—amebic dysentery. Here not infrequently the diarrhea from emetin is confused with the amebic diarrhea, and the drug is continued or increased to a dangerous degree. The same errors may arise in the attempt to treat non-amebic dysenteries with emetin. Here the diarrhea not yielding and later being increased by the emetin, a poisonous effect may unwittingly be secured.

In the use of emetin in China I have seen a few cases of mild poisoning. One group has been noted. Another variety exhibits itself in an exaggerated local reaction to the hypodermic injection of emetin with extreme pain, swelling, erythema locally, and stiffness lasting for several days. The preparations used were uniform with those used in other cases where no such symptoms developed. Such cases suggest the probability of an idiosyncrasy to emetin, and this must always be held as a possibility in constitutional symptoms of poisoning. This view is further supported by the observation in Sollman's Textbook of Pharmacology, p. 309, that certain individuals are so sensitive to ipecac, that a jar opened at a distance of several feet will produce violent sneezing and discomfort. Low (*B. U. J.*, Nov. 13, 1910, p. 176) has noted the same thing as of not infrequent occurrence, and in consequence he prefers intramuscular to hypodermic injection, believing that thus the local reactions are eluded. Whether or not this idiosyncrasy partakes of the nature of

a specific body sensitization, it is impossible as yet to say.

It has been noted by many observers that emetin poisoning gave a clinical picture indistinguishable from acute beriberi. Various physicians in China have seen this occurrence. Levy and Rowntree have collected 20 reported cases of emetin poisoning, including two of their own, in twelve of which peripheral neuritis of varying degree was a prominent symptom. Peripheral neuritis is not an infrequent complication of bacillary dysentery, and is also seen in no small percentage of cases of amebiasis. The possibility, therefore, must not be overlooked that a beriberi or pseudo-beriberi condition may arise in dysentery and be credited to emetin. The fact must be borne in mind, however, that beriberi is common in China and in many other districts where dysentery flourishes, and that an acute dysentery may conceivably determine the onset of an acute beriberi in an individual already the subject of a vitamin deficiency, and also that emetin itself may be the provocative agent. The subject of the nature and mode of action of the exciting factors in acute beriberi have by no means received the attention they deserve. J. Preston Maxwell, in Fukien Province, South China (*C. M. J.*, July, 1915, p. 283) records his observation that a neuritis very similar to beriberi may follow dysentery. He reports such a case in a student of his own, who was cured by emetin of an amebic dysentery accompanied by neuritis. Later he had a second dysenteric attack and received exactly the same emetin treatment, plus a diet of unpolished rice. No neuritis developed. However, on the evidence at hand, muscular weakness, peripheral neuritis and depression of the central nervous system must be put down as possible accompaniments of emetin poisoning, especially in beriberi localities, even though the diagnosis of beriberi should be considered conjointly, inasmuch as the emetin may have been an exciting cause for the development of the neuritis.

In one of Levy and Rowntree's patients, who died, there was marked evidence of renal insufficiency, with nitrogen retention, acidosis and low phthalain excretion. But this may have been only partly excited by the emetin. Autopsy findings showed a luetic aortitis, chronic aortic endocarditis, dilatation of the heart, chronic passive congestion of the viscera, arteriosclerosis, chronic colitis, healed tuberculous lesions of the lungs, and bronchopneumonia. Manifestly these could not all be charged to emetin, yet the implication is clear regarding the possible danger of using emetin in such conditions.

The symptoms obtained by Levy and Rowntree in animals correspond to the clinical picture in human beings. Extreme muscular weakness, lethargy, vomiting, intense diarrhea, and the characteristic circulatory changes were

observed. The characteristic lesion in dogs was the marked gastro-intestinal inflammation.

These same authors make a contribution of particular importance in their demonstration of considerable variation of toxicity in the commercial emetin supplied by the following firms: Burroughs-Wellcome and Company (ampoules), Eli Lilly and Company (ampoules), Merck (crystals), Parke, Davis and Company (ampoules), Sharpe and Dohme (hypodermic tablets). The clinician then must regard emetin with respect, particularly when he recalls such opinions as that of Lyons (*Amer. Jour. Med. Sci.*, 1915, p. 97): "Too large doses or too prolonged use of moderate doses may cause a diarrhea or be responsible for its persistence. There is increasing evidence that large doses of emetin are not without ill effect." Vedder, too, says (*A. M. A.*, 1914, p. 501), "I wish to point out the possible danger in not using due caution in the use of this very potent remedy." To repeat, then, the emetin so far available for clinical use is not a pure alkaloid, and as supplied commercially it has a dangerous variation in toxicity. With this it needs re-emphasis that emetin has dangerous potentialities, and that the utmost caution is necessary in its clinical use.

It is evident that the question of dosage is of supreme import, and here there is considerable diversity of opinion, which is not to be wondered at in the light of the data already presented regarding the variations in commercial emetin. Rather than discuss the voluminous literature in any detail, it may be better briefly to summarize an opinion based on the writings of eminent authorities combined with some personal experience. Ordinarily the dose of emetin for an average adult should not exceed one grain in one daily hypodermic injection. After a course lasting from six to eight days, an interval of one week should elapse, and then two thirds the previous number of injections in the same dosage should be administered. Children show a relative tolerance for the drug, and so far no cumulative effect has, to my knowledge, been reported. For oral infections Bass and Johns recommend  $\frac{1}{2}$  grain daily for from three to six days. The duration and intensity of treatment are to be gauged according to the results of frequently repeated stool examinations. If marked benefit is not obtained with the course as outlined, it is probable that the diagnosis is incorrect or that the amebiasis is a complication. There is a certain danger in using too small doses in that the amebae may become more or less immunized and depressed without being destroyed, and thus become encysted and the condition unimproved. In fulminating cases it is possible that intravenous injection might be required, in which case  $\frac{1}{2}$  grain in a large diluent of saline should be the standard dose.

## USES.

**Amebic Dysentery.** The predominant use of emetin is in the treatment of amebic dysentery, and the history of the empirical use of ipecac, combined with the demonstration of the specific amebicidal action of emetin, places its use here on solid footing. In using emetin in dysentery it is important to recall that if there is to be benefit, it will usually appear early, ordinarily by the third or fourth day. Emetin seems specific in direct proportion to the acuteness of the attack. There is considerable variety in the methods of treatment of dysentery, and the subject is one of much importance, but we are concerned here only with the use of emetin. It may be said, however, that emetin must be supported by symptomatic treatment, as represented in correct diet, catharsis, rest, etc. Chronic dysentery and ameba carriers, as a rule, are uninfluenced by emetin directly, although even here there are certain favorable reports.

Low (*Jour. Trop. Med. and Hyg.*, Feb. 1, 1916) has recently published two cases of chronic ameba carriers which were treated with emetin under careful observation. Both showed the presence of numerous cysts of *Entamoeba histolytica*. These were gradually decreased in number by persistent treatment, although at first no change was seen. Finally even the cysts disappeared, whether or not permanently, the author cannot yet say. Low compares the action of emetin on the amebic cysts to that of quinine on subtertian crescents. Both are resistant to the drug. Continued administration, however, destroys the successive crops of vegetative forms in each case, and thus gradually decreases the number of cysts and crescents respectively, and eventually eliminates the infection.

**Tropical Abscess.** Amebic abscess of the liver may arise with no history of dysentery, in cases where the liver is predisposed, as by chronic congestion, fatty degeneration, or alcohol. In any case, emetin has a very definite use in the pre-suppurative stage, especially when this follows directly on an acute dysentery. After actual abscess formation, the condition becomes surgical although even then emetin may be a valuable adjuvant, particularly if the abscess has ruptured and spread amebae through the contiguous tissues. Usually the diagnosis of full-blown abscess indicates drainage, although improvement and even cure have been reported subsequent to aspiration and the relief of the local congestion by the acupuncture.

**Pyorrhea.** The work of Bass and Johns (*N. O. Med. and Surg. Jour.*, November, 1911) on amebic pyorrhea, which appeared in 1914, is too well known to need repetition. In spite of the difficulty or inability in fulfilling Koch's requirements of specificity, it has been abundantly substantiated that amebae are intimately

related to pyorrhea. Here, too, it is beyond our province to discuss the treatment of pyorrhea, except in so far as emetin is to be employed. Whether emetin alone will cure pyorrhea is an open question. It will, without doubt, cure the amebic infection, and to this end its use hypodermically and locally is indicated. But it cannot be said that emetin is a specific for pyorrhea, that emetin alone will cure it, or that pyorrhea cannot be cured without the use of emetin. These remarks are applicable also to certain bony and oral abscesses and infections other than pyorrhea. Passing mention should be made of amebic tonsillar infections which may be related to hyperthyroidism. Given the pathogenic ameba, emetin is the specific remedy for the ameba, provided the infective agent is not walled off in an abscess.

**Expectorant.** Ipecac enjoys a well-deserved reputation as an expectorant, where by virtue of the milder symptoms of nausea, which it excites, it causes a flow of bronchial secretion, coats over irritated, dry, inflamed membranes, and has a definite beneficial effect. In so far as emetin excites mild nausea, it shares in this action. Wild called attention to this use of emetin in bronchitis and catarrhal affections of the respiratory tract in 1895 (*Phar. Jour.*, L, p. 435, 1895). Evidently the old emetin, with its contamination of cephaelin or ipecamin, would serve better for this purpose than the purified alkaloid. Also, in the light of our increased knowledge of the pharmacology of the ipecac alkaloids, the older galenic preparations would seem to have certain definite advantages over emetin itself for this purpose.

**Hemorrhage.** Emetin has been lauded as almost a specific for hemorrhage in certain chronic diseases, especially for hemoptysis in pulmonary tuberculosis. Some have advocated it as a remedy for hemorrhage in typhoid, diabetes, and other conditions. There is no experimental evidence that emetin has the slightest influence on hemorrhage directly, or that under any circumstances it promotes coagulation. The observation of Howell has been quoted, that emetin in animals causes a soft, jelly-like clot, with no fibrous structure, and that the coagulation time is notably prolonged. These definite data are pitted against no small number of purely clinical observations, with no scientific controls, and even with no careful appraisal of concomitant treatment, or of the possibility of the very frequent improvement which occurs spontaneously in hemorrhage in spite of or without any form of treatment.

It is to be remembered that emetin lowers the blood pressure and weakens the heart. Thus, together with a depression of the central nervous system, which is caused, it might well be said, to increase the tendency to hemorrhage, but this is not the case, for the very use of emetin in spontaneous hemorrhages has been

orrhage. Kunkel (quoted in *A. M. A.*, Nov. 13, 1915, p. 1730) recalls an earlier belief that emetin caused anemia of the lungs and therefore tended to relieve hemoptysis and to have a beneficial effect on pulmonary tuberculosis. He traces this belief to the observation that the pulmonary vessels of animals killed by emetin were empty, a condition really attributable to splanchnic dilatation and drainage of the blood from the lungs. This explanation of the effect of emetin on hemoptysis thus calls in the lowered blood pressure of emetin, but goes on to claim pulmonary anemia as beneficial, when the opposite is now recognized, as, for instance, the rare association of pulmonary tuberculosis with a leaking left heart.

The idea of emetin as a remedy for hemoptysis originated apparently in France. Flaudin and Joltrain, for example, made a report in the *Presse Médicale*, in April, 1913, regarding the value of emetin in tuberculosis. Raeburn, in the *British Medical Journal* in the following year (p. 703), followed with an enthusiastic report which speaks for itself. He divides his cases for emetin treatment into three groups: 1. Bronchitis, where no tuberculosis could be demonstrated. If the heart was in good condition, these cases usually showed improvement, which generally continued after the emetin was stopped. This is surely far from conclusive, as the natural rejoinder is that if ipecac had been used in the place of emetin, improvement might well have been still faster. 2. Cases of clinical tuberculosis with no tubercle bacilli in the sputum. Raeburn here admits that improvement might have been charged to diet and hygiene, but thinks there was a really beneficial action in the congestive stage. 3. Cases with tubercle bacilli in the sputum. Here his results were much less regular, and he draws no conclusion of specific improvement. One may conclude justly that the emetin showed its only beneficial effect in the cases of bronchitis and in tuberculosis where the bronchitic symptoms were prominent, and that it was the expectorant action of emetin which aided, and not any direct influence on the tuberculous disease. In some twelve cases of hemoptysis in which emetin was administered, all in advanced pulmonary tuberculosis, I have failed to see any favorable effect which could not be explained by other factors more plausibly than by the emetin.

To summarize, then, in so far as emetin has a beneficial action in tuberculosis, it would seem to be due to its expectorant properties, and if so, other preparations are preferable. In so far as emetin has a beneficial action in hemorrhage, it would seem to be due to the indirect result of decreasing blood pressure, and if so, other drugs would be more effective, in that they would produce a similar result more safely and without the specific action of emetin on coagulation.

*Constipation.* Levy and Rowntree make the

suggestion, which can hardly be taken seriously from the clinical point of view, that emetin enemata would subserve a useful purpose in the treatment of constipation. Such enemata have an undoubted value when properly used for the sake of the amebicidal action of the drug, but their use as here suggested does not seem well advised.

*Other Conditions.* Like all new and widely noted remedies, emetin has been tried and commended in a great variety of diseases. But it will hardly replace Leonard Rogers' hypertonic infusion in Asiatic cholera. And few of its other applications will bear the test of careful experimentation. It has proved serviceable in the treatment of certain other diseases caused by animal parasites, especially protozoans, but the major uses have been described under its amebicidal action.

### PERIPHERAL NEURITIS FOLLOWING EMETIN TREATMENT OF AMEBIC DYSENTERY.

By A. R. KILGORE, M.D., SHANGHAI, CHINA.

[From the Harvard Medical School in Shanghai, China.]

It is generally accepted\* that emetin hydrochlorid has three main by-effects when used in large single doses or over a considerable time in moderate doses:

(a) *Dizziness or Nausea*, or both, coming on almost immediately after injection (especially intravenously). These symptoms pass off in a few minutes to a few hours, and we have found no serious results reported following single doses of gr. ii (.13 gm.) or less. Baermann and Heinemann<sup>2</sup> report alarming symptoms after doses of gr. v to vii (.3 to .4 gm.) intravenously,—“general vascular paralysis, severe dyspnea, loss of consciousness with vomiting, passage of thin stools and great slowing of the pulse.”

(b) *Diarrhea*. This may follow single large doses, but is usually the result of several moderate doses. Low<sup>4</sup> states that diarrhea not uncommonly occurs after five or six days of treatment with doses of gr. i to gr. ii (.065-.13) a day, but that it always stops when the emetin is omitted. The diarrhea produced by emetin may be severe enough to give stools containing blood and mucus.<sup>2</sup>

(c) *Peripheral Neuritis*, usually manifesting itself by general muscular weakness and pain, often especially marked in the legs, sometimes going on to complete wrist- and toe-drop. Vedder does not mention this complication. Lyons reports a case of his own in which 16 daily doses of gr. i 2/3 (.10 gm.) were given subcutaneously. During the latter part of the

\* The literature on emetin has been recently reviewed in several very complete papers.

treatment the patient had some muscular weakness, but especially weakness and pain in the calf muscles. Lyons also collected a few other cases from the literature,—one, reported by Eshleemann, in which "severe peripheral neuritis with general purpura" developed after receiving gr. ii (.13 gm.) a day for six days. Levy and Rowntree, in an article which has just been published,\* collected the reported cases of ill effects following emetin,—twenty altogether, including 13 cases showing symptoms of neuritis varying from muscular weakness to paralysis. Seven of these thirteen were from the clinic of Dr. E. H. Hume at the Yale Hospital, Changsha, China (report to be published later). During the past few months, in conversations with physicians from other places in China, I have learned of several other cases of varying grades of severity. Peripheral neuritis following emetin is apparently more common (in China, at least) than has been generally supposed, very possibly because the tendency lately has been to give rather larger amounts than the gr. i (.065 gm.) a day for a week to ten days, as originally suggested by Rogers and others.

The following cases are reported, both to call attention to the frequency of peripheral neuritis after emetin, and also because some of them show unusual features,—five of the cases being in one family, and another case showing a skin hyperesthesia instead of the usual muscular weakness and pain.

**CASE 1.** (Red Cross Hospital No. 158.) A white man of 38, who had had recurring attacks of amebic dysentery for eight years and had received a course of emetin six months before admission (how much he did not know). He was given gr. vi (.36 gm.)\* in four doses intravenously. Three months after his discharge from the hospital in Shanghai, he was admitted to the Massachusetts General Hospital,† stating that he had been obliged to take an average of one dose a week of gr. ii (.13 gm.) during the three months to prevent recurrence of the dysentery. Shortly after the beginning of the emetin treatment he began to have pain in the calves, and soon in all his muscles, especially noticeable in the calves, shoulder muscles and neck. At the time of his admission, two weeks after his last dose of emetin, he was still complaining that the muscles of his thighs were unstable and painful and very easily fatigued. "A few days ago his wife fell down and he ran to help her, but his legs gave way beneath him and he fell, too."

On examination his tendon reflexes were normal. He had some tenderness on pressure over the thighs.

No other cause was found for the symptoms (such as alcohol, lead, syphilis, arsenic or trichiniasis), and the pain and weakness cleared up noticeably during his stay of a week in the hospital, no more emetin being given.

This patient developed his first symptoms of neuritis after a total of between gr. x and gr. xx (.65-

1.3 gms.) of emetin had been taken and they were kept up without much change for three months by taking an average of gr. ii (.13 gm.) a week.

**CASE 2.** (R. C. Hosp. No. 732.) A white man of 32 was given six doses of emetin intravenously of from gr. i to gr. ii each. After leaving the hospital, he took "several doses" of gr. ii each intramuscularly, and after a few days reported that he had general muscular weakness and pain, which went on to complete wrist- and toe-drop. The symptoms lasted for several weeks after the emetin was stopped, but finally cleared up, leaving no traces.

A year later, he was again admitted with a relapse of his amebic dysentery and was given a total of gr. x (.6 gm.) during a week and discharged. Ten days later he again had diarrhea with blood and mucus in the stools and took gr. v (.3 gm.) in four doses. Two days after the last dose, he developed a peripheral neuritis similar to the previous attack except that it was not so severe. There was general muscular weakness—a tendency to drag the toes and difficulty in extending the wrists.

The symptoms in this case began after a total of approximately gr. xv to xx (.95-1.3 gm.) for the first attack and after gr. xv (.95 gm.) the second time. It is significant that the second time, though no symptoms appeared after the first gr. x had been taken, yet after an interval of ten days, an additional gr. v brought on the neuritis.

**CASES 3, 4, 5, 6.** (R. C. Hosp. Nos. 733, 734, 735, 736.) These were all children of the last patient (Case 2). They were admitted with him on his second admission, were given emetin, discharged, had relapses and were given more emetin at the same time as their father. All developed marked muscular weakness within a day or two after the last emetin had been given and the dysentery cleared up. The symptoms were especially marked in the leg muscles, so much so that they could climb stairs only with difficulty. Pain was present, but was not so marked as in the father. Unfortunately none of these cases was in the hospital for observation while the neuritic symptoms were present, and it is therefore impossible to report the condition of the reflexes.

The total amounts of emetin given in the hospital and later, with the ages of the patients, are as follows:

Case.	Age.	Total Emetin	Single Dose
3	8	gr. vi (.36)	gr. 2.3 (.04)
4	7	gr. xss (.36)	gr. 2.3 (.04)
5	5	gr. iv (.25)	gr. 1.2 (.03)
6	4	gr. iv (.25)	gr. 1.2 (.03)

All of the emetin in these four cases was given subcutaneously.

**CASE 7.** (R. C. Hosp. No. 957.) A Chinese man of 21. He was given gr. xv (.9 gm.) of emetin in daily doses of gr. i, some of the doses being intravenously and some subcutaneous. On the evening of the last day of the treatment he had a severe chill, sensations over both feet and legs, and tremors. This was present next morning, but cleared up. Then he became ill again, with a severe chill, which interfered with his work, and a general muscular weakness, which was not relieved by rest. He was given gr. vi (.36 gm.) of emetin subcutaneously on the following day, and the symptoms cleared up. He was discharged on the following day. All of the emetin was given subcutaneously.

\* The preparation used in all the cases was Parke, Davis & Co. emetin hydrochloride, sublin tablets.

† During my internship on the service of Dr. R. C. H. I met him whom I am indebted for permission to report this case.

finally became unable to walk at all on account of the pain and tenderness.

On examination, there was tenderness to pressure over the soles of both feet. There was no tenderness or pain in the calves or in other muscles. There was no disturbance of sensation to temperature or touch. There was no edema. Knee jerks normal. No plantar reflex obtained.

No more emetin was taken and the symptoms gradually cleared up during the course of about a month.

#### EXPERIMENTAL WORK.

Levy and Rowntree<sup>5</sup> have made a résumé of the literature and an exhaustive experimental study themselves. The points of interest may be briefly summarized thus:

1. The toxicity of emetin varies widely in the various preparations on the market, and even in different lots of the same preparation.

2. The toxicity when given intravenously varies with the dilution and the rapidity of injection, as well as with the amount, and with individual susceptibility. Comparatively small doses given quickly in concentrated form are more toxic than large doses, given slowly in very dilute form.

3. The principal toxic effects in experimental animals correspond with those noted in clinical work,—vomiting soon after large doses, diarrhea after repeated doses, etc. In dogs there is a lowering of the blood-pressure, marked even when non-fatal doses are given. A cardiac arrhythmia is sometimes produced, shown by electrocardiograph to be a coarse ventricular fibrillation. Respiratory effects are noted only just before death. There is interference with the blood-clotting mechanism,—the coagulation time being delayed. Albuminuria occurs incessantly.

Dogs show at autopsy a gastroenteritis,—often hemorrhagic, with marked congestion of the abdominal organs.

Dale<sup>6</sup> also, in a preliminary note, reports that cats and rabbits die after repeated moderate doses, and that kidney and liver lesions have been demonstrated, but he has not yet described them in detail.

In the literature available, no report has been found of the production of peripheral neuritis with emetin in experimental animals. Experiments on dogs, to be reported later, have been begun at this laboratory, with this end in view. So far, some of the dogs have died with gastrointestinal symptoms, and with lesions obviously corresponding to those obtained by Levy and Rowntree and others, without developing symptoms of neuritis. One dog, however, showed a quite definite paresis of the hind legs for 24 to 48 hours before death. This dog had received doses somewhat smaller than the others. We hope, therefore, by varying the size of the doses,

and perhaps by finding susceptible animals, to produce a peripheral neuritis which may be studied.

#### SUMMARY AND DISCUSSION.

1. Peripheral neuritis after emetin is not uncommon.

2. The symptoms most commonly met with in post-emetin neuritis are general muscular pain and weakness, usually most pronounced in the legs, sometimes going on to paresis. One case is here reported of hyperesthesia of the soles of the feet without other symptoms.

3. The neuritic symptoms often develop after the emetin injections have been stopped, and may grow progressively worse for some time, with no more administration of the drug.

4. The total amount of emetin necessary to produce neuritis varies greatly. The total amounts received by the cases recorded by Levy and Rowntree and those reported here are as follows:

		Grains.	Grams.	
(a)	Adult	19.5	(1.25)	Severe neuritis.
(b)	"	6.	(.39)	Severe neuritis.
(c)	"	21.3	(1.40)	Mild neuritis.
(d)	"	12.8	(.85)	Moderate neuritis.
(e)	" about 10.		(.65)	Mild neuritis.
(f)	"	15.	(.95)	Moderate neuritis.
(g)	Age 8	6.	(.39)	Mild neuritis.
(h)	" 7	5.5	(.36)	" "
(i)	" 5	4.	(.26)	" "
(j)	" 4	4.	(.26)	" "

On the other hand, many patients receive larger amounts and have no symptoms. On going over the records at this hospital for 18 months, it was found that one white patient had received gr. xiii (.85 gm.), three Chinese had gr. xi to xii, and one gr. xxi (1.35 gms.) with no symptoms of neuritis recorded.

5. The prognosis is good. The symptoms clear up gradually, usually over several weeks, leaving no traces apparent.

6. Experiments (now in progress) suggest that peripheral neuritis may be produced by emetin in healthy dogs.

# DYSTONIA MUSCULORUM DEFORMANS— OPPENHEIM'S NEW DISEASE OF CHILDREN AND YOUNG ADULTS.\*

BY ISADOR H. CORIAT, M.D., BOSTON.

*First Assistant Visiting Physician for Diseases of the Nervous System, Boston City Hospital; Instructor in Neurology, Tufts College Medical School.*

IN 1911, Oppenheim<sup>1</sup> described a new and peculiar disease occurring in young people of Russian or Galician Jewish parentage, which he termed *dysbasia lordotica progressiva* or *dystonia musculorum deformans*. On the basis of four cases he attempted to separate the disorder from the tics, athetoses and the various muscular spasmodic states occurring in hysteria. At first the racial predilection of the condition suggested a comparison with amaurotic family idiocy, in fact so much so, that in 1912 Bergman<sup>2</sup> was enabled to make the rather positive statement that "the disorder has up till now been observed only in patients of Jewish extraction." More recent studies have shown that while the disease is pre-eminent among young Hebrews, yet it is not absolutely limited to them, as a few cases have been reported in Christian subjects. Since Oppenheim's original contribution, cases have been published by Belling,<sup>3</sup> Fraenkel,<sup>4</sup> Ziehen,<sup>5</sup> Schwalbe,<sup>6</sup> Flantau,<sup>7</sup> Haenisch,<sup>8</sup> Abrahamson,<sup>9</sup> Bernstein,<sup>10</sup> and Bergman.<sup>11</sup> Nearly all of these cases have occurred in young Jewish children.

The disorder presents many striking features which have hitherto been undescribed. The diagnosis is rather difficult to make, and can be determined with certainty only after long observation. In fact, all who have observed the disease emphasize the diagnostic difficulties. The clinical picture of the condition seems to lie between hysterical scoliosis or *dysbasia*, *idiopathia bilaterale athetosis* and infantile pseudobulbar palsy. The Merzbacher-Pelizaeus syndrome (aplasia axialis extra-corticalis congenita) may also occasion some confusion, but the strongly organic nature of this disorder and the hereditary predisposition ought to clear up the diagnosis.<sup>7</sup>

The real nature of the disease is doubtful. Two of my cases, for instance, resembled hysteria, while the third, which I had the opportunity to study over a long period of time, possessed certain features which suggested an organic basis for the disorder. Oppenheim is inclined to believe that the condition is organic rather than functional, principally, it would appear, on the basis of his previous work on infantile bulbar paralysis with athetosis, and

on the practically negative results of psychotherapy. However, since hypnosis was the only psychotherapeutic procedure utilized, the failure of hypnotic suggestion does not militate against the functional nature of the condition, since, up to the present, no case has been submitted to a complete psycho-analysis. Djerine<sup>12</sup> classifies the condition under the athetoses. I am inclined to believe that we may be dealing with two separate groups of disease pictures, fundamentally different, but identical clinically, and which further observation and study may perhaps separate.

The fact that the disease appears in the children of unaffected parents shows, that like amaurotic family idiocy, a recessive factor is at work. Although no specially strong familial trait can be demonstrated, yet one of my cases had a brother who seemed to possess an abortive form of the disease, but which has not progressed for the last two years. In Schwalbe's description of a similar disturbance, three of the cases were sisters, which would suggest a familial tendency to the disorder. The disease usually occurs in children between the ages of eight and fourteen, although since Oppenheim's original paper, the condition has been reported in young adults, one of my cases being twenty-eight years of age.

The clinical picture is strange and peculiar. The onset is slow, involving first either the upper or lower extremities, and appearing either as tremor of the arms, spasticity of the legs or some disturbance in gait. The gait is stiff and hypertonic; there may be a cross-legged progression or it may resemble that of a muscular dystrophy. One of my patients waddled like a duck. The gait may be similar also to the *dysbasia lordotica* of hysteria, and it was this circumstance which led to the condition being interpreted by Ziehen as a tonic torsion neurosis or as a pure hysterical disturbance. Twisting of the spine, tilting of the pelvis, lordosis and lardo-scoliosis are marked. Characteristic of the condition is the fact that the muscular disturbances tend to diminish or cease when the patient is at rest, but reappear very rapidly as soon as there is any attempt at voluntary movement.

There is a very rapid muscular fatigue in walking. Some of the muscles, particularly those of the neck, show a marked hypotonicity, causing the head to fall forward on the chest. While the patient is at rest, peculiar movements of the limbs may take place, not particularly athetoid or choreiform, but partaking of the nature of both. Such movements are inconstant, however. A combination of rigidity and tremor may also be found. There is no paralysis, atrophy, electrical changes, sensory disturbances, involvement of the sphincters, cranial nerve paralysis, speech abnormalities or mental disturbance. The condition of knee jerks is inconstant; they may be diminished, normal or

\* Read before the Forty-third Meeting of the New England Pediatric Society, March 31, 1916.

† For a minute study of this disease see Merzbacher's original monograph, published in 1910. Also in English "An Unusual Type of Hereditary Disease of the Nervous System," by F. E. Mitten and D. Wilkinson, *Brain*, 1914.

even exaggerated. Facial grimacing has also been observed, and in one of my cases, attempts at voluntary movements of the upper extremities brought out a condition suggestive of a cerebellar disorder.

That the condition had been observed for some time before it became elevated to the dignity of a nosologic entity, is shown by the following passage from the fifth edition of Oppenheim's text book, which was published several years before the appearance of his description of the disease. The reference is to a disturbance of the gait in hysteria, and it will be observed that this description bears a striking resemblance to his later account of dystonia musculorum deformans. "In one of my cases, which followed influenza, the waddling gait was exactly like that of dystrophy; the patient would not keep the trunk erect in sitting, but had to support it with her hands. The paralysis was localized in the lumbar-pelvic thigh muscles, but there was no atrophy or pseudohypertrophy, and the influence of suggestion made its hysterical nature evident."<sup>13</sup> Thus it will be observed that, even before the symptoms had been studied in a group of cases, the condition was considered a pure neurosis, pre-eminently of an hysterical nature.

For the present, the true nature of the disease must remain in the dark, partly because of insufficient clinical material and partly because neither pathological reports nor complete psycho-analyses are available. Evidently the disorder is not purely hysterical, since suggestion has been ineffective in ameliorating the symptoms, and none of the cases seemed to follow an emotional shock. One of my cases, however, showed certain characteristics of a traumatic neurosis, while the other occurred in a highly neurotic Hebrew patient. If the condition is hysterical, future investigations will probably clear up its psychogenesis; if organic, the lesion is probably in the putamen and the caudate nucleus, the same as Oppenheim and Vogt<sup>14</sup> found in certain cases of infantile bulbar paralysis with athetosis. The precipitating causes of the disorder are somewhat clearer, and suggest a certain analogy with hysteria. In Flatau's two cases, for instance, the condition followed an injury to the leg; in one of Schwalbe's cases, it appeared after an emotional shock; while in two of my cases emotional factors in the etiology could be incriminated to a certain extent.

The following three cases came under personal observation:\*

CASE 1. A., age 9, a Russian Jewess, was the eldest child of parents free from any neurotic tendency. She was always well with the exception of measles. A week following a fall down two steps, in which she did not complain of any injury at the time, she began to walk "crooked" but without any

complaint of pain. At first the right foot was affected, but under the application of a plaster-of-Paris bandage, in a few days she walked without any further evidence of a limp. At the time the diagnosis of hysteria was made. Shortly after the application of the plaster bandage was made, she began to walk lame again. A neurological examination at that time revealed the following symptoms:

Grasps good, strength and movements of arms normal. Movements of leg joints free. She walks with a marked contraction of the muscles of the right calf, but when lying down the contraction disappears. The knee jerks are lively and equal and there is a patellar twitch on both sides. Plantar reflexes normal. No Babinski. Testing of the knee jerks or sometimes manipulating of the leg at the ankle joint, produces a contraction of the calf muscles. Pupils normal. There is no disturbance of sensation to touch or pain. Tenderness in both iliac fossae, particularly on the left. No tenderness along spine.

The condition remained about the same for nearly six weeks. A tenotomy of the hamstring muscles was ineffective in altering the muscular spasm. An examination at this time revealed a tendency to hyperextend the right leg at the knee and to rotate the right leg outward in walking. Voluntary movements at the ankle, knee and hip joints can be performed, but rotation of the leg brings on a muscular spasm. Shortly afterwards the condition became decidedly worse. For several weeks, she was unable to sit down, since when, placed in a normal sitting posture, the body assumed the position of an opisthotonic arc de cercle, with jerky movements of the buttocks. In walking, she repeatedly jerked the body backwards and walked in a waddling duck-like manner, with the knee and hip semi-flexed. The right knee joint was particularly the seat of a strong contraction and she was unable dorsally to extend the foot. Unfortunately, this patient disappeared from observation and could not again be traced.

CASE 2. B., male, age 29, Russian Hebrew, upholsterer. The family history is negative except that the father had been a sufferer from chronic bronchitis for a number of years. He had worked steadily at his trade and there had never been any serious physical disease. Married six years, three healthy children, the youngest of whom was ten months old. There was a history of coitus interruptus for years on account of poverty. For four years there had been a complaint of a sensation of numbness of the left side of the body, without, however, in any way interfering with his work.

Several days previous to being seen, without any definite precipitating cause which could be ascertained, he suddenly began to suffer from peculiar attacks of trembling and a disturbance of gait. These attacks were not constant, but took place perhaps every fifteen minutes or so. In the normal interval, any sudden noises, even music, sudden changes of position, or the swallowing of food would produce an attack. The voice became weak and hoarse, he appeared easily frightened, with a facial appearance of extreme anxiety, and he was constantly looking to his family for sympathy, which, needless to state, made the attacks more severe and frequent. There were no gastric disturbances and with the exception of over-anxiety, the mental condition was normal.

*Examination.* Trembling of the entire body with

\* Case 1 is from the Neurological Department of the Boston City Hospital (service of Dr. Thomas). Cases 2 and 3 were seen privately.

a facial appearance of distress, weakness and anxiety. He whimpers a great deal, speaks in a weak voice, which at times becomes a hoarse whisper, resembling a partial hysterical aphonia. Observation shows peculiar attacks of muscular spasm influencing the position of the body and the gait. These attacks strongly resemble an hysterical dysbasia lortotica. The attacks begin with a look of distress and anxiety, then a trembling of the entire body, and in an attempt to walk he throws the head backwards, walks very slowly with a marked lordosis of the spine, particularly in the lumbar region, bending of the knees and balancing movements of the arms. Under these conditions the gait becomes waddling, like that of a duck, and at times it is strongly suggestive of a muscular dystrophy. In the attack after an initial tremor of the trunk and limbs, the arms and legs become rigid and spastic, the spasticity being of the tonic variety. The muscles of the spine also become spastic and it is this spasticity that produces the lordosis. The contracted and spastic muscles become rapidly fatigued, the spasm then slowly relaxes and the attack ceases after five to ten minutes. Even between the attacks, however, there remains a certain amount of a lordotic dysbasia with rigidity of the spinal muscles and a tendency to bring the edges of the scapulae close together. It seems as if the muscular fatigue were responsible for the cessation of the individual attacks and as the fatigue disappears, a new attack takes place. The attacks can also be produced experimentally by sudden noises or by sudden changes of position of the body and tend at times to cease when they are ignored by indifferent questions, even at the height of the attack and before the onset of the muscular fatigue. No difficulty in swallowing and no globus. No tachycardia in the attacks. The condition is most liable to take place on attempts at walking, since when he lies down the muscular spasm relaxes.

The pupillary reactions and the ocular movements were normal and there is no nystagmus. Visual field not contracted. Tongue central and tremulous. No tremor of the outstretched hands. Knee jerks and Achilles jerks much exaggerated. Double spurious ankle clonus. No sensory disturbances to pain or touch. Sphincters normal. Heart negative. No paralysis.

Under the administration of bromides, rest and suggestion, with purposeful neglect of the symptoms, the dysbasia disappeared within a week's time and has not since returned after more than six months.

#### CASE 3. C., age 7, a Russian Jewess.

*Family History.* All the ancestors were born in Russia and it is interesting to note that the family had the same social background of poverty, mental anxiety and persecution, as has been observed in my studies on amaurotic idiocy. Grandparents healthy. On the maternal side an uncle has tuberculosis, an aunt is neurotic, another uncle suffers from chronic lead poisoning, while a paternal aunt has been hemiplegic since childhood. When the mother was six years old she had to work hard, and up to eleven years of age had scarcely enough to eat. At eleven, she sewed as a dressmaker's apprentice and during her entire life she has been under a severe physical and mental strain under conditions of extreme poverty. The father has also been under a severe strain all his life, yet both father and mother show no evidence of any neurosis and are physically strong and healthy. There are five children in the

family. The mother has had no miscarriages. The two children who are younger than the patient, likewise a sister who is one year older, are strong and healthy. The eldest brother, act. 13, shows a tendency to nystagmus, and has slightly unequal pupils and knee jerks. He has no muscular spasm or tremor. The patient is the third child. Since the descent of the disorder is through similarly unaffected stock, the condition must be due to a recessive factor according to the scheme of Mendelian inheritance.

*Personal History.* The child walked and talked at a normal age and was well and strong up to shortly after she was five years old. Following a tonsillectomy, tremor of the right hand and a stiffness of the left foot was noticed. Then she began to stagger in walking and running, locomotion became cross-legged, the head bent to the left and began to shake and a marked curvature of the spine developed. No incontinence of urine or feces. No headache, vomiting, abnormal salivation or blindness. No complaint of pain and no hyperacusis. No evidence of mental deterioration.

*Examination.* The child is well nourished and of normal size for her age. No signs of any mental deterioration. As the child sits up, which she can do only with assistance, the head falls to the left and shows a fine tremor, there is a marked kyphosis of the dorsal spine and also a lumbar lordosis. While the lower spinal muscles appear to be spastic, yet the hypotonia of the neck and cervical muscles is so marked that the head falls forward on the chest. The thigh and hamstring muscles are in a condition of hypertonia, likewise the anterior tibial group, thus keeping the big toe of each foot in a condition of hyperextension. She can walk only with assistance and then the gait is of the cross-legged projection type. The adductors of the thighs are in a state of spasm. Right thigh rotated outwards and left thigh rotated inward, thus tipping the pelvis to a certain extent. There is no muscular or fibrillary twitching.

As the child is at rest, but becoming greatly increased on voluntary movement, there are observed constant, restless and slow choreiform movements of the arms. In attempting to grasp objects, the choreiform movements of the arms became jerky, discontinuous, awkward, and associated with a coarse tremor and ataxia, resembling the dysmetria of cerebellar disease. The tremor is absent during repose, but the choreiform movements are constant, though less marked than on attempts at voluntary movement. All attempts at movement produce a rapid fatigue. Thus the peculiar restlessness is much reduced when the patient is quiet, and becomes markedly visible only on voluntary movement.

A further analysis of the movements of the arms revealed the following: Constant restless and slow choreiform movements of both arms. On account of the muscular spasm, she is unable fully to open the left hand, which remains semi-flexed. On attempting to grasp a tumbler, the movements of the right arm became jerky, discontinuous, excessive, and likewise very awkward, resembling the condition seen in hereditary ataxia or after destruction of the cerebellum in monkeys.

Pupils equal and react promptly to light and accommodation, both directly and consensually. No nystagmus. Fundi normal. No muscular atrophy. Speech normal. No facial palsy. Tongue central, without tremor. Knee jerks exaggerated and equal. No Babinski or Oppenheim reflexes, although co-

stimulation of the right plantar surface, there is an inconstant and apparently voluntary extension of the big toe. Achilles jerks absent. No ankle clonus. No sensory disturbances to pain or touch could be demonstrated, even on the most careful testing with von Frey's hair esthesiometer. On attempts at exertion the child perspired profusely and became rapidly fatigued. No hyperaesthesia.

The patient was kept under observation for about a year. During this time the peculiar movements of the arms on voluntary movement became more marked and the hypertonicity of the muscles, particularly of the legs, increased, finally rendering walking impossible. With all this, there was no muscular atrophy, abnormal reflexes or mental deterioration. The neck muscles, however, remained hypotonic. Speech became somewhat bulbar and indistinct and there was a moderate degree of drooling of saliva, without, however, any atrophy of the tongue or difficulty in swallowing. None of the muscular incoordination was increased when the eyes were closed. Massage, motor re-education and the use of sedatives, were ineffective in ameliorating the condition.

In discussing this material, which, unfortunately, is small on account of the rarity of the condition, several factors stand out prominently. All the patients were of Russian Jewish origin, and their ancestors had been subjected to physical strain and persecution, the same ancestral history which we have found in our investigations of amaurotic idiocy. In two of the cases the family history was negative; in the third, certain neurotic tendencies were clearly defined. In all the cases, the disorder appeared in the descendants of unaffected stock, thus corresponding to a recessive condition, according to the Mendelian laws of heredity. Here again the comparison with amaurotic idiocy is rather striking.

The first two cases strongly resembled an hysterical dysbasia, but without any corresponding sensory disturbances; in the third case there was evidence of some organic affection of the nervous system as shown by the spasticity, the gait, the bulbar symptoms and the variations in the muscular tonicity, yet lacking the usual pathological reflexes of the spastic group of diseases. This latter case possessed certain features which were strongly suggestive of a Friedreich's ataxia, but after prolonged observation, it seemed warranted to place it in the group of the dystonias. In one case the condition followed a slight trauma, in another it appeared after a tonsillectomy, while in the third, it was engrafted on a highly neurotic and probably latent hysterical individual.

The prominent features in all the cases were the peculiar gait, the changes in the muscular tonicity, and the rapid onset of the disease without any pathological reflexes or changes in sensation. All reported cases of the disease show that it begins in an extremity: in our first case in the right foot, in the second case in the leg, in the third case in the right hand and left foot. The onset in this latter

patient exactly resembled the beginning of the disease in Flautau's two cases, and on which he lays considerable diagnostic emphasis.

The disorder presents certain difficulties of diagnosis because of its obscure relationships to hysteria, on one hand, and to organic diseases of the nervous system on the other. For this reason it is difficult to place the condition in any definite nosological entity at present. Possibly we may be dealing, as suggested at the beginning of this paper, with a varying pathological condition, but with an identical clinical symptomatology.

## Society Report.

### NEW ENGLAND PEDIATRIC SOCIETY.

A MEETING OF THE NEW ENGLAND PEDIATRIC SOCIETY WAS HELD AT THE BOSTON MEDICAL LIBRARY ON MAR. 31, 1916, THE PRESIDENT, DR. A. C. EASTMAN OF SPRINGFIELD, IN THE CHAIR.

The following papers were read:

- I. DYSTONIA MUSCULORUM DEFORMANS, OPPENHEIM'S NEW DISEASE OF CHILDREN AND YOUNG ADULTS.\*

By ISADOR H. CORLIAT, M.D., Boston.

- II. FURTHER EXPERIENCES WITH HOMOGENIZED OLIVE OIL MIXTURES.

By MAYNARD LADD, M.D., Boston.

- III. A STUDY OF FIRST EXAMINATION, WITH A REPORT OF FIFTY CONSECUTIVE PHYSICAL AND MENTAL EXAMINATIONS OF SO-CALLED WELL CHILDREN.

By WILLIAM R. P. EMERSON, M.D., Boston.

#### DISCUSSION.

DR. BARRON (Dr. Emerson's paper): I have a few statistics along the line of Dr. Emerson's investigations which I would like to present to the Society.

\* See JOURNAL, page 383.

Dr. Howard, and lately I have been associated with him, has been carrying on somewhat similar work during the past 15 months. We have records of 176 examinations of children, varying in age from three to four years up to 17 or 18. Of those 176 children, 165 have defects, or 93+%. Of those who have more than one defect there are 108= at less than 62%. The total defects of the 176 children equal 354; out of these 354, 145 were remediable, such as carious teeth, tonsils and adenoids, and things of that sort. I looked up the statistics this morning and they apparently show as high a percentage of defects as the children which Dr. Emerson has seen at the Little Wanderers' Home. In addition to these we have a large number of children under two years, some of whom would undoubtedly add to these total figures. From present indications the tabulated results of these examinations indicated data of sufficient value to warrant publication later.

Dr. STONE (Dr. Emerson's paper): I have brought with me just a few figures to represent some of the work which is being done by the school physicians of Providence along the lines of Dr. Emerson's paper. The examinations have been made of children who have been in school one-half year. All are examined, being stripped to the waist. We do not make vaginal examinations; 3926 pupils were examined in the school year of 1914-15, and of these, 1018 showed defects of sufficient importance to require notification of parents or guardians; the number of defects was 3894, which meant from one to four defects each in these 1018 children. Hypertrophied adenoids and tonsils constituted the largest number of defects, 782 children, or 19.9% of those examined being thus affected; 226 had anterior nasal obstruction and 407 had defective vision; 604 were recorded as having malnutrition or anemia and 158 had enlarged glands. These were the most important defects found. Decayed teeth are not recorded by the school physician because we have a dentist who makes a separate examination and report. He examined 4554 children during the school year of 1914-15 and found 4000 with carious teeth.

Dr. CORIAT (Dr. Emerson's paper): I would like to have Dr. Emerson explain the relation of nasopharyngeal obstruction to mental retardation. I believe that nasopharyngeal obstruction may cause a certain amount of retardation in children, but if there is any organic substratum which would lead to idiocy or feeble-mindedness, I believe then that the nasopharyngeal obstruction is merely an incident in the physical examination and bears no relationship whatever to the degree of mental retardation. In cases of idiocy or feeble-mindedness which I have had the opportunity to observe after the removal of adenoids and tonsils, a secondary examination according to the Binet-Simon test showed absolutely no improvement in the mental condition. I believe, therefore, that in a great many of these statistics there is a tendency absolutely to confuse the issue.

Dr. SMITH (Dr. Ladd's paper): I was very much interested in hearing Dr. Ladd's further reports on this particular method of feeding. I should like to ask if in Dr. Ladd's experience this method of feeding helps in any way to establish a tolerance for other kinds of fat? I have used it in a few patients, and it seemed to me in one instance after using the olive oil that subsequently that child was able to take other fats better. What is the method of getting children off of this kind of food on to other food—is it done abruptly or gradually?

Dr. TALBOT (Dr. Ladd's paper): I did not quite

catch in discussing the subject whether Dr. Ladd said all the milk was heated or not. The question has come up in my mind (I think I asked the same question last year) how much heat was generated in the process, and whether the very fact of homogenization did not cause some sterilization of the milk and in that manner change the digestibility of the casein. I have used this method in a few instances, and in one instance we had very brilliant results. In other instances the results were exactly the opposite—and my results have not been uniformly as good as those Dr. Ladd reports.

Dr. EASTMAN (Dr. Ladd's paper): Has Dr. Ladd used this method of feeding in fat eczema, and does the eczema yield to this type of food?

Dr. LADD (in closing): In answer to Dr. Smith's question as to whether this method of feeding increases the tolerance for other fats, I think that it does if continued long enough. It depends a great deal upon the severity of the indigestion and the length of time the child has been vomiting. There are one or two cases in this series where the house officer, in changing the formula, failed to indicate that the fat was olive oil. At the next visit the child had lost in weight and the vomiting had returned. The milk was changed to olive oil and the vomiting stopped and the gain in weight was resumed. This is very well illustrated in No. 10, a case of pyloric spasm. In this case the milk was stopped for six weeks at one time, and when put back on cow's fat the baby stopped gaining, vomited and had a great deal of fat in the stools. The olive oil feeding was resumed and the vomiting stopped and the child gained 42 oz. in the next 47 days. I have not tried to see how soon I could get them off of olive oil. I have been content to allow them to continue on it to the end of the first year, as the results were satisfactory, and then when the formula has reached a point where it is about that of the strength of cows' milk, I get them on to cows' milk by gradual changes, as a rule, substituting an ounce of cow's milk for an ounce of the modification, then two ounces, and so on, until the whole of the olive oil mixture has been replaced by cows' milk. I do not think, however, that these gradual changes are always necessary. There are some cases where I have had to change at once and have done so very successfully. It depends a good deal upon the length of time the child has been upon the food. The milk was not heated to 212° in all cases. The point which influenced me was the degree of peristalsis which follows the use of maltose. If there is a tendency to looseness of the bowels, a mixture that is boiled is better tolerated than one that is not.

In reply to Dr. Talbot—I stated in my paper that this method has been applied to 38 cases, of which 12 were private and 26 were in the outpatient department. I have not included in this series the older children (three, four or five years) who come into an entirely different class of feeding from infants in the first 12 or 18 months. I have also excluded a case of congenital heart of case and enlarged thymus, and two or three heart diseases have been started recently and are new cases; also one or two who had the milk for one or two days only and then for some reason stopped taking the milk from the laboratory. No cases have been excluded because of any unfavorable result.

In reply to Dr. Eastman—one of the cases (No. 2) had a great deal of eczema during the first seven months of its life, and it cleared up very rapidly after the milk was homogenized. In other cases

which have shown a tendency to eczema, the condition has improved. This result I would attribute more to the improvement in the state of digestion than to any direct action of olive oil.

DR. WALTER B. SWIFT (Dr. Coriat's paper): I have nothing especially of value to say about this condition; I have not looked it up and did not know much about it before I came to the meeting. But as I see everything through the eyes of speech these days, I was wondering if something more could be found and whether the more modern tests for speech trouble have been applied to these cases. Of course, here there is a variety in the degree of the involvement; perhaps in one case there may not have been anything in the speech, but in this last case it seems to me that something else marked and perhaps quite characteristic might show. We know already that there is a sign in the speech which distinguishes tabes from paresis; there is one in chorea; there is also a sign of tic and several others that have been lately put into the literature. These have been brought out by new and modern tests. If these tests had been applied, there might be something pathognomonic about the condition which would show. I have no doubt about the entity of this condition. Oppenheim is a very remarkable observer, and if he puts forth an entity as a new disease, it is pretty authoritative.

DR. TALBOT (Dr. Coriat's paper): Dr. Coriat has laid a good deal of stress on persecution in the forebears of these children. I wonder if Dr. Coriat has ever looked up what happens to the children of other people who have been persecuted. I would question whether persecution itself is as important a factor as Dr. Coriat seems to suggest and I wonder whether control cases have been looked up.

DR. CORIAT (in closing): In reply to Dr. Swift, I would like to say that out of my three cases, the only speech defect was in the last case. In a rather extensive investigation of the literature which I made in preparing this paper, I could find no record of any speech involvement in any of the cases reported. I have no doubt that the disease is a clinical entity. As to its fundamental basis, there is still room for considerable difference of opinion,—some of them seem merely hysterical, and others have features of an organic disorder. But I think the disease is one which, as more cases are observed, will become of increasing importance for the specialist in children's diseases, and they certainly ought to be on the lookout for the condition. I have no doubt that after we begin to recognize the condition, we shall not find it any more rare than amaurotic family idiocy.

As to Dr. Talbot's question, I fully agree with him. I do not believe that persecution has any strong etiological effect in this disease or in amaurotic family idiocy, although in the latter, where I have been able to carry out my investigations to a greater extent, it seems that the disease occurs only in children of the persecuted Jew and never in the children of the non-persecuted Jew.

### Book Reviews.

*Cancer of the Stomach. A Clinical Study of 921 Operatively and Pathologically Demonstrated Cases.* By FRANK SMITHIES, M.D.,

Gastro-enterologist to Augustana Hospital, Chicago; formerly Gastro-enterologist to the Mayo Clinic, Rochester, Minn.; formerly Instructor in Internal Medicine and Demonstrator of Clinical Medicine in the University of Michigan, Ann Arbor; Fellow of the American Gastro-enterological Association, etc. With a chapter on the *Surgical Treatment of Gastric Cancer*. By ALBERT J. OCHSNER, M.D., LL.D., F.R.C.S., Professor of Clinical Surgery in the School of Medicine of the University of Illinois; Surgeon-in-Chief to Augustana Hospital, Chicago; Consulting Surgeon to St. Mary's Hospital, Chicago. Illustrated. Philadelphia and London: W. B. Saunders Company. 1916.

Dr. Smithies' book should be owned by every medical man who is interested in cancer of the stomach, whether viewed from the diagnostic, therapeutic or preventive standpoint. It is the summary of a very great amount of personal work, which has been accurately recorded, and thoroughly studied, and which has been based upon his own wide clinical experience; to this, he adds a vast and sympathetic familiarity with the results of other observers throughout the world.

The book contains about 450 pages of Dr. Smithies' text, based upon more than nine hundred cases of gastric cancer,—cases which have been proved to be cancer by the surgeon and the pathologist. This is supplemented by 50 pages devoted to the surgical treatment, written by Dr. Ochsner.

The book is divided into twelve chapters, including the one by Ochsner; in these chapters are considered,—(1) General Distribution; Etiology; (2) Morbid Anatomy; (3) Symptoms; (4) Abnormalities; (5) Examination of Function; (6) X-Ray Examination; (7) The Blood; (8) Ulcer in Respect to Cancer; (9) Cancer in Youth; (10) Differential Diagnosis; (11) Surgical Treatment; (12) Non-Surgical Treatment. This gives a good outline of the scope of the work, and its method of attack. We would have welcomed the author's own synopsis of each chapter, had he found it possible to append it at the end of each section.

It is evident that Dr. Smithies still believes in the ultimate importance of the clinical diagnosis of cancer, as he says near the end of the chapter on X-ray Examination: "in a majority of cases (of a given series) clinical diagnosis was quite possible without the added x-ray examination; in clinically doubtful cases, the Roentgenographic diagnosis was similarly dubious."

The printing, illustrating and bookmaking are very good.

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States. \$6.50 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager,*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## PROGRESS OF POLIOMYELITIS EPIDEMICS.

DURING the past week there has been, on the whole, a steady abatement of the various epidemics of poliomyelitis. On September 8 the number of cases in New York City reached a total of 8,435 with 2,090 deaths. In New York State outside of New York City there had been, on September 6, a total of 2,401 cases with 255 deaths. In New Jersey from July 1 to August 21, inclusive, there were 2,024 cases. In Pennsylvania from July 1 to September 6 there were 1,004 cases with 260 deaths. Of these, 580 cases and 212 deaths were in Philadelphia. All schools in Pennsylvania are to remain closed until September 18. In Toledo, Ohio, there have been 95 cases with 17 deaths, and the

opening of the schools in that city has been postponed until the same date.

In Massachusetts during the month of August the total number of cases was 257 with 33 deaths. In July there were 107 cases and during the preceding six months only 30 cases. The distribution of these cases is a matter of considerable interest. It has been tabulated by counties and towns as follows:

Barnstable County—Bourne, 3; Orleans, 1; Yarmouth, 1.

Berkshire County—Adams, 4; North Adams, 20; Pittsfield, 10; Savoy, 1.

Bristol County—Dartmouth, 1; Fairhaven, 1; Fall River, 3; New Bedford, 11; Taunton, 1.

Essex County—Amesbury, 10; Beverly, 2; Haverhill, 6; Georgetown, 1; Lawrence, 3; Lynn, 1; Newburyport, 2; Peabody, 2; Salem, 5.

Franklin County—Erving, 3; Greenfield, 2; Montague, 6.

Hampden County—Agawam, 1; East Longmeadow, 3; Holyoke, 7; Southwick, 1; Springfield, 17; West Springfield, 1; Westfield, 3.

Middlesex County—Cambridge, 6; Framingham, 1; Littleton, 1; Lowell, 4; Malden, 2; Medford, 2; Newton, 3; Reading, 1; Somerville, 8; Hampshire County—Easthampton, 5; Hadley, 3; Northampton, 4.

Norfolk County—Braintree, 2; Brookline, 1; Canton, 1; Milton, 3; Norwood, 1; Stoughton, 3; Plymouth County—Abington, 1; Plympton, 1; Wareham, 4; Whitman, 1.

Suffolk County—Boston, 36; Chelsea, 1; Revere, 4.

Worcester County—Blackstone, 1; Douglas, 1; Dudley, 3; Fitchburg, 4; Hopedale, 1; Barre, 1; North Brookfield, 1; Leominster, 1; Southbridge, 4; Sturbridge, 1; Uxbridge, 2; Webster, 1; West Boylston, 1; Worcester, 5; Milford, 1; Lancaster, 1; Charlton, 2.

It will be observed that the largest number of cases has been in Boston; but North Adams, with 20 cases, has had a far higher percentage incidence, and with eight deaths has had by far the highest mortality in the present epidemic. There have been seven deaths from the disease in Boston. During the first nine days of September, 104 cases of poliomyelitis were reported in Massachusetts. There have now been sixteen cases each in Holyoke and Pittsfield, and fourteen in Amesbury since the outbreak of the epidemic. There have been a together 86 cases in Boston, 31 in North Adams, and 21 in Worcester. The Boston School Committee has voted as a precautionary measure to postpone the opening of the public schools in this city until September 25. Similar postponements have

taken place in many cities of this Commonwealth and in several of the higher institutions of learning. In many towns, however, it is planned to open the schools on the usual date.

Among the other New England States, only Connecticut has had more cases than Massachusetts. In Rhode Island there were 56 cases during the first seven months of the year with nine deaths, and 46 cases with 8 deaths since July 22. In Manchester, N. H., four new cases and three deaths were reported on September 4.

The first death of a physician from poliomyelitis during the present epidemic was that of Dr. Earl C. Peck of Newton, Mass., who died on September 5, while serving as assistant resident physician at the municipal hospital in Philadelphia. He had been engaged in the care of poliomyelitis patients. His obituary notice is published in another column of this issue of the JOURNAL.

In New York the Health Commissioner is at present devoting particular attention to the after-care of patients convalescent from poliomyelitis, and to the possible relation between this disease and the paralyzes affecting domestic animals. The following plan has been adopted by the Department for collecting data with reference to this relation:

In order that exact information may be posted as to whether poliomyelitis occurs in domestic animals, and, if so, whether the latter play any part in the transmission of the disease, all the nurses in the department, now visiting cases of poliomyelitis, have been instructed to make a special inquiry regarding animals. If they find anything suspicious they will report the matter immediately and the suspected animals will be removed by the Department of Health for observation. A veterinarian will then be sent to examine the animal, and if the suspicion is justified, the animal will be killed and an anatomical examination made.

In addition to this, arrangements have been made whereby a veterinarian of the Department will visit the shelter of the Society for the Prevention of Cruelty to Animals to see whether any suspected cases of animal infection are there encountered. In this investigation the Bureau of Preventable Diseases will have the cooperation of the Bureau of Laboratories and of the United States Public Health Service.

In Chicago the Commissioner of Health has appointed a committee, consisting of Dr. N. Herzog, Dr. K. Meyer, Dr. H. B. Thomas, Dr. A. Hoyne and Dr. A. K. Armstrong, to undertake research on poliomyelitis in that city.

## SHIPMENT OF POISONOUS DRUGS BY MAIL.

THERE has recently been introduced in the United States Congress, at the instance of the National Association of Manufacturers of Medicinal Products, a bill to amend Section 217 of the United States Criminal Code relating to the shipping of poisonous substances by mail. This bill (Senate 6834, House 17396) is known as the Kern-Doremus Bill, from the names of its proponents in the two houses. The present section of the Criminal Code above referred to forbids absolutely the transmission of poisonous drugs, even for legitimate purposes, by mail. This prohibition may prevent the mailing of emergency preparations ordered by physicians from a distance by telephone or telegraph. It has seemed to the advocates of the Kern-Doremus Bill that this article should be amended so as to exclude only drugs not outwardly or of their own force dangerous to life, health, and property and to permit the shipping by mail of poisonous drugs not thus dangerous if securely and properly prepared and packed, so as not to endanger the mails or those handling them from leaking or breakage. In accordance with this feeling the new bill has been drawn in part as follows:

"SEC. 217. All kinds of poisons and all articles and compositions containing poisons which are outwardly or of their own force, dangerous or injurious to life, health or property; and all other poisons, and articles and compositions containing poisons so insecurely packaged as to endanger the mails or those handling them from leakage or breakage, all articles and compositions herein described that are not packaged and prepared for the mails in accordance with any regulations that may be made by the Postmaster-General for their preparation and packing; and all poisonous animals, insects, and reptiles, and explosives of all kinds, and inflammable materials, and infernal machines, and mechanical, chemical, or other devices or compositions which may ignite or explode, and all disease germs or scabs, and all other natural or artificial articles, compositions, or materials of whatever kind which may kill, or in any wise hurt, harm or injure another, or damage, deface, or otherwise injure the mails or other property, whether sealed as first class matter or not; and all spirituous, vinous, malted, fermented, or other intoxicating liquors of any kind are hereby declared to be non-mailable matter and shall not be conveyed in the mails or delivered from any post office or station thereof, nor by any letter carrier."

The remainder of the bill provides penalties for violation of these provisions. The Postmaster-General is empowered to make suitable regulations respecting preparation and packing for the mails.

The intent of this proposed amendment seems just and the bill in question has been endorsed by the American Pharmacæutical Association and the American Association of Pharmaceutical Chemists. Its discussion and further consideration will presumably be postponed until the next session of Congress.

### PYORRHEA ALVEOLARIS AND ITS TREATMENT.

THE issue of the JOURNAL for August 10 was devoted largely to a series of papers dealing with different aspects and opinions relative to hay fever and its treatment. In the present issue of the JOURNAL is published a shorter series of papers relating to pyorrhea alveolaris and its treatment by bacterial vaccines or by emetin, and with some other applications of emetin therapy. Dr. Medalia, whose previous paper on this subject appeared in the issues of the JOURNAL for December 19 and 26, 1912, believes the vaccine treatment superior to that by emetin. Dr. Reed, dealing less particularly with the use of emetin in this condition, reviews the history of the drug and presents a valuable summary of its pharmacological and toxic action and its therapeutic uses. Dr. Kilgore's paper offers interesting clinical evidence of one of the complications that may follow emetin therapy.

The recognition that the teeth and their adjacent tissues may afford ready and frequent portal of entry for systemic infections is one of the important advances in medicine during the past decade. It now appears probable that this portal is really less through the tooth itself than by way of the tissues immediately surrounding it in the alveolar socket. It is not yet determined beyond question whether the infection leading to pyorrhea alveolaris is specifically due to the endameba buccalis or may be caused by ordinary pyrogenic organisms. That emetin is a specific amebicide is established beyond doubt and this drug has at least found a definite therapeutic place in the treatment of amebic dysentery. If pyorrhea be really a specific amebal infection, emetin should be also its specific drug. Unless this is definitely proved,

however, it would seem that the use of emetin in this disease should hardly be continued, inasmuch as emetin is a drug whose exhibition is attended with not infrequent inconvenience and occasional danger.

### MEDICAL NOTES.

MUNICIPAL CLINICS FOR SCHOOL CHILDREN.—The Department of Health of the City of New York has recently issued a reprint of the report of its free municipal clinics for school children, which were held in that city from 1912 to the end of 1915. During this time 1,677 children were examined and of this number, 1,605 required treatment. The closing of these clinics by the Health Department will force the children back to the dispensaries where, among crowded conditions, the manner of operation and individual attention cannot be of the highest efficiency.

While some institutions refuse to perform operations for hypertrophied tonsils and adenoids without complete anesthesia, because of lack of facilities for the proper care of the patients after operation, a large number of the dispensaries (including out-patient departments of several noted hospitals) operate upon the children in the general clinics and without anesthesia. To this is added the great risk of sending the patient home without any precautions being taken to prevent secondary hemorrhage or septic infection of the throat. This element of danger in the treatment of nose and throat cases was taken into account by the Department of Health in planning the school children's clinics. Not only must all operations be performed with complete anesthesia, but every care and precaution have been introduced from time to time.

In view of these facts the Bureau of Welfare for School Children has made recommendations to the proper authorities that these clinics be continued and suggests the use of the seven municipal halls for the housing of such clinics.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The twenty-sixth annual meeting of the American Electro-Therapeutic Association was held in New York City on September 12, 13 and 14. Among the many papers presented was one by Dr. Fred H. Morse of Boston on "Currents in Electro-Therapeutic Applications" and one by Dr. Frank B. Granger of Boston on "The Condenser Discharge in Diagnosis and Treatment." Dr. George E. Doering of Worcester, Mass., presented a paper on "The Treatment of Sub-Acromial Bursitis."

RESEARCH IN TROPICS.—Dr. E. E. Linwood Walker, associate professor of tropical medicine at the University of California, Los

been sent by the George Williams Hooper Foundation to South America, to carry out investigations on tropical diseases on the upper Amazon. Dr. Walker will be stationed 1,500 miles from the mouth of the river in the region of Porto Zelho, where a hospital is maintained by the Madeira-Mamora Railroad under the directorship of Dr. Allen M. Walker. In the laboratories of this hospital, researches on the parasitic infections of man in the tropics will be conducted.

**CHANGES IN DRUG PRICES.**—Report from New York on August 28 records a few recent minor changes in the cost of drugs. Quinine has declined 10 cents in manufacturers' hands. Glycerine has moved up to 36@37½ cents per pound. Benzoic acid has advanced to \$10@ \$11 per pound. Various important coal tar preparations have moved up owing to increasing scarcity. Salol and the salicylates are exceptions to this rule, however, the tone being easier owing to lower priced offers of carbolic acid, the base product. Camphor has been in unabated demand from smokeless powder and celluloid manufactures and the outlook favors further advances.

**BRITISH MEDICAL ASSOCIATION.**—At the recent formal meeting of the British Medical Association in London, Dr. Sir T. Clifford Allbutt was elected president of the association for the ensuing year. Dr. Allbutt was born on July 20, 1836.

**PLANS FOR NEW YORK HOSPITALS.**—In the issue of the New York Times for August 28 are recorded the plans now formulated for the rebuilding and remodeling of the Sea View Hospital for Tuberculosis on Staten Island and the Children's Hospital and Schools for Mentally Defective Children on Randall's Island, New York. A total of \$1,400,000 has been appropriated for this purpose. Mr. John A. Kingsbury, commissioner of the New York Charities Department, is reported as follows in regard to conditions and plans at the Randall Island Hospital.

"Some of the buildings in which the patients are housed were constructed in 1848, and many of them were built before 1860. These buildings have thin brick walls, with small windows and damp, unventilated basements, wooden floor beams, and wooden floors. The wood of these floors, as the result of daily scrubbing for generations, is decayed, offensive, and insanitary. The pipes for the heating and plumbing are worn out beyond repair.

The Commissioner's plans provide for two large infirmaries, with day rooms, one for girls and one for boys, inclosed in glass, on the south, with terraces where the children who cannot walk may be wheeled out to sit in the air and

sunshine. In these buildings will be housed all crippled and those unable to care for themselves. The buildings will also be equipped with special bath slabs, upon which crippled children may be bathed comfortably and without danger. A special system of heating will be installed.

Two cottages are also planned for the inmates who are of a higher grade of mental development. A dining and an industrial room will be provided in the basement of these cottages. The dormitories will be flooded with light and air through maximum window spaces on three sides. The construction will conform to the strictest rules of fireproofing. For the nurses, investigators, and teachers a small attractive dormitory will be provided. There will also be a house for the medical staff.

At Sea View Hospital, the problem is entirely different. That hospital was opened in 1913 with a capacity of 1,000 beds. It is composed of unusually costly pavilions, constructed primarily for bed patients, for which the construction cost per bed was nearly \$4,000. The new plans contemplate doubling the capacity of the hospital in order that it may be possible to give immediate care to the large number of tuberculosis patients, many of whom are now obliged to wait for weeks before a vacancy can be found.

The 1,000 additional beds are to be provided in twenty-one open cottages of fireproof construction with forty-eight beds to a cottage. These cottages will furnish accommodations for 400 additional women patients and 600 additional men patients. There will also be a group-building for men, with a dispensary, industrial rooms, billiard and recreation rooms and a general lounging room. There will also be a big dining hall receiving 600 men, which will be so constructed that all the tables can be run out into an adjoining room, and the hall used for entertainments.

The plans for both Randall's Island and Sea View Hospitals have been entirely completed and have been approved by all the necessary official bodies, except the Board of Estimate."

#### EUROPEAN WAR NOTES.

**WORK OF AMERICAN PHYSICIANS IN GERMANY.**—In the issue of the New York *Staats-Zeitung* for July 1 is published an account of the work done by American physicians and surgeons during the past year in war hospitals in Germany and Austria. In 1915, the American Physicians' Expedition Committee organized and opened a large reserve hospital at Oppeln in Silesia and since that time has not only conducted this hospital, but has established and maintained three others in Germany and two in Austria. The article by the Berlin correspondent of the New York paper describes the character of the work done at these institutions in part as follows:

"The American Hospital at Deutsch-Eylau in West Prussia handles all the surgical cases that

come from the front to the Deutsch-Eylau reserve hospital, which has 1,800 beds. It also does all the surgical work for the large garrison. Furthermore, it gets all the surgical cases among the civil population of the town, where there are no more surgeons, as all are at the front; all those from the garrison towns of Reisenburg, Rosenberg, and some other places and those among the civil population of a great many neighboring towns.

"You may easily imagine what a huge amount of work the Americans do there and can willingly believe them when they say that when large fresh convoys of wounded are brought in they have to work night and day in order to complete their tasks. When I was in Deutsch-Eylau recently I saw the official records which show how large was the number of cases in which sick civilians had been turned over to the head doctor of the American hospital with a request for treatment. The rush to the 'Herrn American doctor' on the part of the civil population is so great that it is simply impossible to dispose of all the cases.

"The American Physicians' Expedition Committee has at present, as I am officially informed, six of these large war hospitals in operation, four in Germany (Oppeln, Deutsch-Eylau, Naumburg an der Saale and Coblenz) and two in Austria-Hungary. Two of them are financed by Chicago and one by Milwaukee. I asked the official to tell me plainly if the American doctors really were welcome and if they were needed.

"The American hospitals are filled to the limit," I was told. "So you may see for yourself if we need them and how we trust them. Are they welcome here? We honestly wish that people would send us still more of them. The more the better."

"The equipment of the American hospitals is really ideal. Economy is the order of the day, but considerable sums are spent for instruments and apparatus that are necessary. The orthopedic department of the hospital at Oppeln is the best in the entire province of Silesia, and the things that have been done there already verge on the miraculous. The many wounded men there, whose limbs have been restored to use, will never in their lives forget what they owe to American willingness to aid. Many a one who otherwise would have remained a cripple all his life will be in a position after the war to earn his living as he did before.

"The most friendly relations were soon established between the Americans and the local doctors, as well as the officers of the garrison. The Americans are invited to all the social affairs, and are regular guests at the casino and at the family tables of the best people of the city.

"The people of Germany will not forget the work of the American Physicians' Expedition."

**DEATHS OF BRITISH PHYSICIANS IN THE WAR.**—Report from London states that during the year

from August 1, 1915, to August 1, 1916, over four hundred British physicians died of disease or were killed in action in the war.

**WAR RELIEF FUNDS.**—On September 9 the totals of the principal New England funds for the relief of the European War reached the following amounts:—

Belgian Fund . . . . .	\$151,372.74
French Wounded Fund . .	118,099.25
Serbian Fund . . . . .	102,348.07
Armenian Fund . . . . .	66,594.10
Polish Fund . . . . .	42,669.67
Belgian Tobacco Fund . . .	35,092.50

#### MEXICAN NOTES.

**RED CROSS GERMAN HOSPITAL.**—To finance the complete equipment of an American Red Cross base hospital unit which is being organized by the Military Relief Department of the Red Cross with a staff from the German Hospital in New York, a contribution of \$25,000 has just been given by Mr. Fritz Achelis, 9 East 57th Street, New York City. The Director of this unit will be Dr. Frederick Kammerer, who recently withdrew from active service with the German Army and brings to his new task the valuable knowledge gained at the German front in Europe. The following letter has been forwarded to Mr. Achelis by Maj. Gen. Arthur Murray, U. S. A. (Ret.), Acting Chairman of the Central Committee of the American Red Cross:

"This office has just received information from the Red Cross Chapter in New York that you have donated \$25,000 to purchase the equipment for the base hospital unit which is to be organized in connection with the German Hospital in that city. I desire to thank you for this fine manifestation of patriotism and public spirit in the name of the American Red Cross, which will carry out your humane intentions; and also for the American people, who will benefit by them. It is believed that there can be no more practical and useful way in which the Red Cross spirit of humanity can be put into practical operation than by making such preparations for the care of the wounded in war as to insure our soldiers in future, if the calamity of war should come, against a repetition of the unnecessary suffering and loss of life which has occurred from the lack of such preparations in all our wars heretofore."

**MORBIDITY AMONG UNITED STATES TROOPS.**—Report from Washington, D. C., states that during the week ending Sept. 2, the morbidity rate among regular and national guard troops at the Mexican frontier was 2.5. During this period there were six deaths from disease, of which five were malignant.

**MASSACHUSETTS VOLUNTEER AID FUND.**—On September 9 the total fund of the Massachusetts Volunteer Aid Association for relief of soldiers at the Mexican frontier, and their families, reached the amount of \$75,760.65.

#### BOSTON AND NEW ENGLAND.

**THE WEEK'S DEATH RATE IN BOSTON.**—During the week ending September 9, 1916, there were 232 deaths reported, with a rate of 15.91 per 1,000 population, as compared with 204 and a rate of 14.31 for the corresponding week of last year. There were 53 deaths under 1 year as compared with 51 last year, and 55 deaths over 60 years of age against 53 last year.

During the week the number of cases of principal reportable diseases were: diphtheria, 25; scarlet fever, 13; whooping cough, 18; measles, 10; typhoid fever, 8; tuberculosis, 38.

Included in the above were the following cases of non-residents: diphtheria, 7; scarlet fever, 5; tuberculosis, 1.

Total deaths from these diseases were: diphtheria, 3; tuberculosis, 27; whooping cough, 5.

Included in the above were the following deaths of non-residents: tuberculosis, 4.

**TYPHOID FEVER IN LYNN.**—During the past 3 weeks there has been a small epidemic of typhoid fever in Lynn, Mass. Several cases were reported on August 28, and on September 8, the total number had reached 72. The source of the outbreak has been traced to an infected milk supply.

**PREVENTION OF BLINDNESS IN MASSACHUSETTS.**—In the recently issued report of the Massachusetts Commission for the Blind are given in detail the efforts of the field agent to eliminate eye disablement and blindness caused by syphilis. He states as follows:

"That syphilis was responsible for fully 6 per cent. of our new cases of blindness became evident after a study of eye records dating from a time (1908-09) when methods of diagnosis were much less precise than they are now. A review of a group of 98 cases of practical blindness referred to this Commission during the past year shows that 9 per cent. were diagnosed as syphilitic. This result, while based on too few cases to be conclusive, indicates at least that the earlier estimate was not excessive. Old cases of blindness known to the Commission—especially cases of that prolific cause of blindness, atrophy of the optic nerve—are now, moreover, not infrequently found to be of syphilitic origin. Merely indicative though they are, these facts point to the need of more thorough study. Only on a basis of such investigation can new work for the saving of eyesight from syphilis be planned.

A valuable beginning has been made by Dr. Abner Post and Dr. George S. Derby in an in-

tensive study of congenital syphilis in its relation to that serious and too common eye disease of youth,—interstitial keratitis. This study, promoted by the Commission for the Blind, and financed by the Perkins Kindergarten for the Blind, has already shown in part what can be done to save children's eyes from the more serious effects of this disease. Its continuance through another year may throw some definite light on whether the eye disease, interstitial keratitis, can itself be prevented by early and adequate treatment of its underlying cause,—congenital syphilis.

With the object of securing further knowledge of syphilis, as a basis for preventive work among adults as well as children, the Commission for the Blind voted, Dec. 17, 1914, to make the following suggestions for the consideration of the Commissioner of Health and the Public Health Council: 'That cases of syphilis among inmates of public institutions, such as reformatories, insane asylums, etc., be made reportable direct\* to the State Department of Health, as a first step toward a State-wide study of this cause of blindness and other troubles.' It was the feeling of the Commission for the Blind that this reporting might go hand in hand with work by the State Wassermann Laboratory for the diagnosis of syphilis.

While the proposed action has not yet been taken, the Commissioner of Health has publicly proposed furnishing salvarsan, or some equivalent, free to physicians who report cases of syphilis (as in New York, by office number rather than by name). This action, for which there is a precedent in the furnishing of antitoxin, and of preventive for ophthalmia neonatorum, would be taken less with the idea of securing a permanent cure of each reported case of syphilis, than with the purpose, and reasonable prospect, of checking the contagious stage of the disease, thus destroying many foci of contagion, and limiting the spread of this menace of eyesight, sanity and life itself.

The carrying out of this policy, in connection with the rapidly growing work of the State Wassermann Laboratory, will involve increased appropriations. In this instance, however, even greatly increased expenditure will be a wise investment of the public funds,—an investment certain, in fact, to be many times repaid to the public in the increased earnings—to say no more—of the living, sane and seeing people saved from this infection."

The Commission reports further that during the twelve months ending November 30, 1915, only one new case of total blindness from ophthalmia neonatorum has been discovered in the State. While, of course, there may be other cases not known, it is safe to say that, through the co-operation of the State Department of Health, the local health boards, the Massachusetts Chari-

\* Authority for such action is given by Chapter 670 of the Acts of 1913.

table Eye and Ear Infirmary, the Society for the Prevention of Cruelty to Children and others, the menace from this cause of blindness has been reduced from about 5 to less than 1 per cent. as a factor in bringing about loss of sight.

## Correspondence.

### THIRD NEW ENGLAND TUBERCULOSIS CONFERENCE.

*Mr. Editor:* The National Association for the Study and Prevention of Tuberculosis wishes to issue through you a cordial invitation to the members of your medical society to attend the New England Tuberculosis Conference in New Haven, Conn., on October 12 and 13. One of the most important meetings of this Conference will be the medical session. As a program for this session, we desire to arrange, first, that opportunity shall be given for a full discussion of the experiences of individual physicians and medical associations in dealing with the tuberculosis problem. Secondly, we are planning to have one or two formal papers by leading tuberculosis experts. We expect also to devote several other sessions to discussions of the social aspects of tuberculosis. These will include formal meetings of a popular nature and informal round-table talks.

May we ask that you bring this letter to the attention of your society at its next meeting in order that, if it is their pleasure, delegates may be appointed to attend the Conference and take part in the discussions of the medical session and of the other sessions as well.

Very truly yours,

PHILIP P. JACOBS,

*Assistant Secretary.*

105 EAST 22d ST., NEW YORK CITY, AUG. 1, 1916.

### A CORRECTION.

*Mr. Editor:*—

In your JOURNAL of August 17, there is an excellent article by Dr. John Hitchcock on Tuberculosis Dispensaries. In this article, however, there is one statement which I feel needs correction.

Discussing the incipient case which needs sanatorium treatment, Dr. Hitchcock states that at the Rutland State Sanatorium, which is intended for incipient and favorable cases of pulmonary tuberculosis, there are 50 per cent. of advanced cases which, he says, prevents the sanatorium from doing the work for which it was intended. As a matter of fact, during the past year at the Rutland State Sanatorium, there were 12.8 per cent. of patients classified as "advanced" according to the national classification. It is very likely that Dr. Hitchcock has included in his figure not only those patients classified as "advanced," but also those classified as "moderately advanced."

This is hardly a fair statement, as many of our most favorable patients are in the moderately advanced stages when they commence treatment. In justice to the Rutland State Sanatorium and to the excellent work which it is doing, it seems only fair to make this correction.

Very truly yours,

JOHN B. HAWES, 2d, M.D.

29 Gloucester St., Boston, Aug. 21, 1916.

### A PERUVIAN CUSTOM.

PALEMEIRA, BRAZIL, June 29, 1916.

*Mr. Editor:* I take the liberty to send you this letter with prayer of publishing it in your valuable journal, if you find that it might be of some interest to your readers.

Some years ago, traveling through Peru as a missionary, I had the opportunity of learning the secret process by which the Indians of the Capota River, after cutting off the head of their prisoners of war, reduce it to one-sixth, more or less, of its natural size and keep it as a trophy.

Two of such heads can be seen in the Museum of Natural History in London, England; and probably, in the museums of United States also, can be found some specimen of them.\* They are very small, as I said, but the features of the face are perfectly preserved—they look like miniature heads, and keep incorrupt for an indefinite time.

I would like to know if the divulgation of the process by which such extraordinary result is obtained could be of utility in the field of science; or if there is among the distinguished subscribers of the BOSTON MEDICAL AND SURGICAL JOURNAL anyone who is interested in knowing such process. In that case I would be pleased to communicate to him the operation that has been described to me.

Thanking you in anticipation for your courtesy, I am, Sir,

Respectfully yours,

HORACE GIRALDI.

Address:

Rev. Horace Giraldi,

Rector of the Catholic Church,

Palmeira,

(Rio Grande do Sul, Brazil)

\* There are two specimens in the Warren Museum of the Harvard Medical School, Boston.

## Miscellany.

### CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE TWO WEEKS ENDING AUGUST 26, 1916.

August 14.

Surgeon J. F. Leys, detached Fleet Surgeon, Atlantic Fleet, to home and wait orders.

Surgeon A. W. Dunbar, to Naval Academy, Annapolis, Md.

Surgeon C. P. Kindelberger, detached Naval Academy, to Fleet Surgeon, Atlantic Fleet.

Surgeon F. C. Cook, to Naval Training Station, Norfolk, Va.

Surgeon C. E. Riggs, detached Naval Training Station, Norfolk, Va., to Navy Yard, Washington, D. C.

Asst. Surgeon A. R. McAllister, detached Navy Station, Guam, to temporary duty, Mare Island, Cal.

Asst. Surgeon W. A. Vogelzang, detached Marine Hospital, to Naval Station, Guam, September 1, 1916.

Asst. Surgeon Lincoln Humphreys, to Naval Hospital, Washington.

August 21.

Asst. Surgeon O. J. Mink, detached Naval Hospital, Puget Sound, Washington, to home and wait orders.

Asst. Surgeon J. E. Neplerger, M. R. C., to Marine Barracks, Port Royal, S. C., September 1, 1916.

### APPOINTMENTS.

The following Mason Unsett's place, to which he was appointed on August 21 as assistant surgeon of the United States Medical Reserve Corps, at Washington, D. C., Boardman, Dr. George S. Doble, Dr. Walter A. Johnson, Dr. Roger French, Dr. Nathaniel R. Moore, and Dr. James F. Stoddard.

## UNITED STATES CIVIL SERVICE EXAMINATION.

MEDICAL INTERNE, ST. ELIZABETHS HOSPITAL, OCTOBER 4, 1916.—The United States Civil Service Commission announces an open competitive examination for medical interne, for both men and women, on October 4, 1916. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position in St. Elizabeths Hospital (formerly Government Hospital for the Insane), Washington, D. C., at \$900 a year, with maintenance; and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by re-instatement, transfer, or promotion.

The positions are tenable for one year, and pay \$75 a month and maintenance. During the year, however, a postgraduate course in mental and neurological diagnostic methods is given, an examination is held, and promotions to the next grade, junior assistant physician, are made. Beyond this there is regular advancement for men whose services are satisfactory. St. Elizabeths Hospital has over 3,000 patients and about 800 employees to care for. In addition to the general medical practice offered, the scientific opportunities in neurology and psychiatry are unsurpassed.

Applicants must show that they are graduates of a reputable medical college or that they are senior students in such an institution and expect to graduate within six months from the date of this examination. The names of senior students will not be certified for appointment in the event they attain eligibility in the examination, until they have furnished proof of actual graduation. Applicants must not have graduated previous to the year 1914 unless they have been continuously engaged in hospital, laboratory, or research work along the lines of neurology or psychiatry since graduation, which fact must be specifically shown in the application. Applicants must be unmarried. Age, 20 years, or over, on the date of the examination. No sample questions of this examination will be furnished. Applicants must submit to the examiner, on the day of the examination, their photographs, taken within two years, securely pasted in the space provided on the admission cards sent them after their applications are filed. Tintypes or proofs will not be accepted. This examination is open to all citizens of the United States who meet the requirements.

Persons who meet the requirements and desire this examination should at once apply for Form 1372, stating the title of the examination for which the form is desired, to the United States Civil Service Commission, Washington, D. C. Applications should be properly executed, excluding the medical and county officer's certificates, and filed with the Commission at Washington in time to arrange for the examination at the place selected by the applicant. The exact title of the examination, as given at the head of this announcement, should be stated in the application form.

## NOTICE.

## MEMORANDUM IN RELATION TO THE PROPOSED "CLINIC FOR PAYING PATIENTS," TO BE CONDUCTED BY THE MOUNT SINAI HOSPITAL IN COLLABORATION WITH A GROUP OF SPECIALISTS.

The clinic is proposed in the belief that there exists in this city a need for pay clinics where ambulant patients in moderate circumstances, who are not entitled to free treatment, may consult reliable specialists without being compelled to pay office fees which are beyond their means. The clinic does not wish to compete with or to supplant the family practitioner, but aims to afford treatment to patients who are now

neglected, to undermine quackery, and to replace free dispensary treatment by compensated, or at least partly compensated cooperative practice. It is the purpose of the clinic to confine its aid to persons having incomes of \$1200 per annum or less.

(Incidental to the inauguration of clinics in certain special branches of medicine and surgery, it is proposed to undertake the organization of a department for the prevention of disease. The method to be followed in this department will be that of the periodic examination of individuals for the early detection of morbid tendencies, with a view to the prevention or postponement of constitutional disorders.)

Patients will be admitted to the clinic on week days from 7.30 to 9.00 P.M. There will be a registrar whose duty it will be to receive applicants, to reject persons not eligible for treatment, to keep the social, clinical and financial records of the clinic, and to collect and account for all fees. Mount Sinai Hospital contributes the use of its Dispensary Building and equipment. All earnings in excess of necessary expenditures will be divided among the members of the medical staff in proportion to their hours of attendance. The standard fee for routine or office consultation (except in the Department for the Prevention of Disease) will be one dollar. Medicine will not be furnished by the clinic; prescriptions given to patients are to be filled elsewhere as in ordinary private practice. A moderate extra charge will be made for x-ray work, and for any unusual laboratory or other investigation which necessitates the use of costly supplies, or the collaboration of auxiliary workers. The clinic will not seek to derive any profit from such investigation or examination, but only to be reimbursed for any unusual outlay, and to make suitable payment to professional collaborators.

Besides treating patients who come to the clinic of their own accord, or who may be referred by physicians for routine examination and treatment, the members of the staff will be prepared to see patients at the clinic in consultation with general practitioners. It is presumed that cases presented in this way will be such as require unusually careful and complete examinations: the fees to be charged for this consultation work will, therefore, be higher than the regular fee of one dollar to be charged for routine examinations, and may be agreed upon between the practitioner presenting the case and the clinic physician consulted; such special fees should ordinarily be two or three dollars.

## SOCIETY NOTICE.

NEW ENGLAND SURGICAL SOCIETY.—The annual meeting will be held in Boston on October 5, 6, and 7, 1916.—P. E. TRUESDALE, M.D., *Secretary*.

## NOTICE OF MEETING.

On September 20 will be held at Hotel Bancroft, Worcester, a meeting of 5 delegates from each Massachusetts District Medical Society to consider what action may be taken towards securing repeal or amendment of the Workmen's Compensation Act.

## RECENT DEATH.

DR. EARL C. PECK, of Newton, Mass., who died of acute poliomyelitis of bulbar type on September 5 at Philadelphia, was a native of Newton. He received the degree of M.D. from Jefferson Medical College in 1914, and later became resident physician at the Germantown Hospital. In 1916 he was appointed first assistant resident physician of the Philadelphia Municipal Hospital, and was serving in that position at the time of his death.

#### THE RAT AND INFANTILE PARALYSIS: A THEORY.

BY MARK W. RICHARDSON, M.D., BOSTON.

FROM 1909 to 1914, I was Secretary of the Massachusetts State Board of Health and was, therefore, intimately concerned in the investigations made during those years in relation to the occurrence in that State of infantile paralysis. Begun in 1907, at the instigation of Dr. Robert W. Lovett, a member of the Board, and continued intensively for a period of five years under his supervision, together with the expert coöperation of Professors Milton J. Rosenau and Theobald Smith, the work of the Massachusetts health authorities represented an activity equalled only by the investigations carried on over a similar or longer period of time in Sweden. Because of their expert character, the Massachusetts investigations have received world-wide acknowledgment for the manner in which they were conducted and for the conclusions drawn from them.

At the International Congress of Hygiene, held at Washington in 1912, it was my privilege to present for the Board the results of the Massachusetts experience for the previous five years, in which presentation I maintained that epidemiological observations in Massachusetts did not bear out the general assumption that the disease was a contagious one in the ordinary sense, in that it was conveyed by direct or indirect personal contact through the secretions of the mouth and nose. Professor Rosenau, furthermore, present-

ed experimental evidence to show that in monkeys, the infection could be transferred through the bite of the stable fly, *Stomoxys calcitrans*, an observation later confirmed by Anderson and Frost. These views, however, were combated by Professor Petterson, representing the Swedish Government, who presented an elaborate brochure defending the thesis that the bodily secretions and excretions are important factors in the distribution of infantile paralysis and that direct and indirect human contact are the determining influences in the spread of the disease.

Unfortunately for the insect and fly theory of transfer, experiments made by a number of observers in the years following 1912 failed to confirm the results of Rosenau and of Anderson and Frost, so that medical opinion has gradually accepted the claims of the Swedish observers that personal contact is the essential element in the spread of the infection. This conclusion is hardly to be wondered at, in view of the fact that the virus of the disease can be demonstrated not only in the secretions and excretions of the sick individual, but also oftentimes in the nasal secretions of healthy persons who have been in association with patients. Then, too, the insect theory, especially as related to the stable fly, did not harmonize with the undoubted fact that it was enter epidemics, though rare, had been reported.

In spite, however, of these contradictory observations, I have never been seriously moved from my opinion that infantile paralysis is not transferred from person to person by direct or indirect contact, but that, in some manner, insects play an important rôle in the epidemiology of this disease.

The arguments in support of my position, I shall present in two categories: first, those arguments which militate against the transfer of infection by direct or indirect human contact, and, secondly, those which support the theory that the disease is transmitted by rats or other rodents, by insects on the rats or rodents, or by both in combination.

*Facts Against its Transfer by Direct or Indirect Human Contact.*

1. Nature of the virus: The virus of infantile paralysis resembles markedly that of rabies, essentially an animal disease. It is not in any way similar to that of tuberculosis, influenza, pneumonia, diphtheria, septic sore throat, all of which so-called sputum diseases are known to be spread through personal contact, and the infected secretions of the mouth and nose. The virus of rabies is widely disseminated through the body and is present in the saliva, and yet, the disease is not transferred from individual to individual except through the agency of a punctured wound. The mere presence, therefore, of the virus of infantile paralysis in secretions and excretions constitutes no proof that these body-products are of importance in the spread of the disease, especially when the great majority of other epidemiological factors are shown to be against such agency.

2. Summer incidence of the disease: The vast majority of cases occur during the spring, summer, and fall, when personal contact is least intimate. With the onset of winter, when the population becomes more and more congested in houses, schools, etc., the disease becomes reduced almost to nothing, whereas most of the above-mentioned sputum diseases occur chiefly in the winter time when congestion of the population is at its maximum.

3. Maximum prevalence of the disease in country districts where personal contact is least intimate at all times.

4. Failure to spread in general hospitals for children in which, up to recent times, cases have been received without let or hindrance.

5. Failure to spread in schools and institutions for children in which single cases have occurred and where personal contact with large numbers of children has been intimate.

6. Extreme rarity of the disease in doctors, nurses, and other attendants upon persons sick with infantile paralysis.

7. Entire absence of infection in laboratory workers with the virus of infantile paralysis. Of course, in these two latter instances, the effect of age is important, but occasional infection would certainly be noted if the disease were markedly contagious.

8. Comparatively rare occurrence of more than one case of the disease in large families of children even under the markedly congested conditions of tenement life.

9. Epidemics cease oftentimes in mid-career, so to speak, when the human material has been

by no means exhausted and the opportunities for direct or indirect contact are at their maximum.

10. Long continued immunity of cities and towns in close commercial relations with infected centres even though interchange of population with possibilities of indirect contact is marked. The city of Springfield, for instance, although in intimate commercial relations with the infected Berkshire district in 1907 and the infected Colrain district in 1908, had practically no cases of infantile paralysis until the epidemic of 1910. A similar situation is noted by Wernstedt, who says, concerning the epidemic of 1911 in Sweden: "It is to a certain degree surprising that in the three counties nearest Stockholm and the county of Stockholm no epidemic occurrence of infantile paralysis can be traced until the epidemic had been raging in Stockholm for several months. In regard to the county of Upsala (next to Stockholm) the epidemic had already raged in Stockholm for two months before the first case of the epidemic was observed in this county, this case being, at the same time, the first observed here during that year." A similar experience was noted in Great Barrington in 1909, where a small but marked epidemic occurred first in September, October, and November, even though immediately adjacent towns of Berkshire County were afflicted during June, July, and August.

11. The Colrain epidemic in 1908 was perhaps the most severe on record, thirteen per thousand of the population being affected, yet according to Emerson, who investigated the epidemic in this and neighboring towns, evidence of contagion was practically lacking.

12. The disease has been noted by many observers to travel radially from centres of infection, and it is very common to find the later cases on the outskirts of the infected area. If third persons or indirect contact were responsible for the spread of the disease, we should expect to have an irregular distribution and to find early as well as late cases on the periphery.

13. Finally must be explained the very important fact that given areas once severely infected are commonly immune for a considerable period of years in spite of the fact that new generations are constantly being born and new susceptible material is being brought in from non-infected neighborhoods. Swedish observers, for instance, have pointed out, in comparing the two great Swedish epidemics of 1905 and 1911, the fact that although the affected districts in 1911 are contiguous to the districts affected in 1905 and have, therefore, apparently some important relation to the older epidemic, the older areas were, in 1911, practically free from the disease even though the newer areas were affected to a maximum extent. The conclusion is, therefore, necessarily to be drawn that the epidemic in 1911 had some intimate connection with that of 1905 though the relation is not clear. In

order to explain the immunity of the old areas, the Swedish investigators have put forward the theory that in 1905 the disease was very much more prevalent than was recognized, so much so in fact that, through the agency of missed and abortive cases, the community in some way not only became immune itself, but, in some unrecognized manner, communicated that immunity to the new-born generations. It is, of course, apparent that this theory is a very far-fetched one. Conceivably such a conclusion might be drawn if there had been in 1905 a severe infection of adults. Children born in the interval between 1905 and 1911 might thus perhaps inherit an immunity, but adults, as a rule, are not susceptible to the disease. This point will be taken up again in a succeeding statement and a theory much more in accordance with the facts will be submitted.

*Facts Supporting the Theory that the Disease is Transferred by Rodents, Insects, or Both.*

Summer incidence of the disease: That poliomyelitis occurs at its maximum in the summer months is a fact which the supporters of human transmission cannot get away from, and one which they, as a rule, glide over with insufficient comment. The resemblance, furthermore, of the disease in its epidemiology to malaria and yellow fever has been noted more than once. Moreover, the positive results of Rosenau and also of Anderson and Frost, together with the successful experiment of Flexner with the bed-bug, made it highly probable that insects might, in some instances at least, be instrumental in the transfer of the disease. In this connection, indeed, a few positive experiences by observers of the first class are sufficient to counterbalance in their evidential value many negative results. That the bed-bug might be the intermediate link in the chain seemed to me highly improbable in view of the fact that infantile paralysis attacks with almost equal frequency all strata of society. In considering, furthermore, the possible agency of the stable fly, it has always been difficult for me and others to explain the undoubted, though rare, occurrence of winter epidemics. Thus, by a sort of elimination, one is brought to a consideration of another epidemic disease, plague, which is known to be transferred, for the great part, through the agency of the rat and the flea, and to be most prevalent during the warmer seasons.

The possible relation of the rat to infantile paralysis was first brought to my attention in 1910 through an observation made by Dr. Charles E. Simpson, State Inspector of Health. In investigating an epidemic of the disease, Dr. Simpson observed the fact that many rats, whose homes had been in a town dump, were compelled, because of a fire in that dump, to seek refuge in the neighboring houses. In these houses infantile paralysis seemed to be mildly prevalent. Another experience pointing in the same direction occurred in a small country neighborhood occu-

pied as a summer colony by a number of city residents. The only immediate unusual factor to be assigned for this epidemic was the removal, from one situation to another, of an old barn. The barn cellar was dug up and improved, and, during this operation, the affected children played in the excavation. The inference is, of course, that many old rat holes were destroyed and that the accumulation of years in the way of rat disease and fleas may have been distributed broadcast to the outside world. A third observation, but a rare one, was made in a Massachusetts city where, in an infected district, many rats were said to have been found dead. In another city a muddy river and its tributaries honeycombed to a greater or less extent the municipality. The location of the cases of infantile paralysis seemed to have a remarkable relation to this stream and its branches. Indeed, the whole Massachusetts experience seems to indicate that the disease has been endemic along its rivers, most of which are polluted by sewage to a greater or less extent. The possible association of the water rat was thus indicated.

If, now, we take the rat and its parasite, the flea, as the hypothetical agents in the transmission of infantile paralysis, how does this assumption fit the epidemiological facts?

1. The rat has a world-wide distribution.
2. It is found in habitations of all classes of the community, rich as well as poor.
3. In the winter time the rat keeps largely to its hole, coming forth in the spring with the advent of warm weather and the growth of appropriate food.
4. Although statistics are unavailable, it seems highly probable that rats are more common in the country, at least in proportion to the population, than they are in the city. In any event, it is not unreasonable to suppose that in ordinary country barns, out-houses, etc., the exposure to rat influence is much more marked than it is in the city where the houses are better built and where sewage and other sanitary provisions are much more complete. In any event, the children are constantly in the barns and numerous cats and dogs might convey infected fleas to the houses. Incidentally, the cats and dogs might become infected. This increased exposure to rat influence might, moreover, explain the higher percentage of adult infection in rural districts, noted by Frost.
5. The great increase in poliomyelitis during the last twenty-five years has been explained as due to the great increase in facility of transportation all over the world, so that infinitely increased human contact has become possible. The same argument would apply, however, to the transfer of infected rats from one locality to another. Indeed such transfer in freight cars and ships carrying grain, cattle, pigs, etc., must be common. This brings us to another consideration

6. That the relation to the railroads of cases of infantile paralysis has been noticed by a number of observers. Nothing could be more probable than that children living near railroads should play in rat-infected freight cars. Infected rats, furthermore, if dropped from freight cars, would necessarily seek their food in the immediate neighborhood. A possible case in point was that of a young college student who contracted infantile paralysis during his summer occupation as a freight brakeman.

7. In the study of the epidemiology of infantile paralysis, it has been a common observation that (a) the disease occurs in foci, (b) in general, the cases spread more or less radially from centres of infection, and (c) the intensity of infection rises in one neighborhood while it is decreasing in a focus in its immediate vicinity. Such a fact is hard to explain through human transmission, which should result in the irregular distribution of cases, but is perfectly consonant with a gradually spreading infection of rodents. The migratory habits of the rat are well known. In New Orleans, Creel found that marked rats set free at a certain point in the city could be trapped considerable distances away in a very short time. Indeed, migrations of large numbers of rats over long distances are on record. The rat would, therefore, satisfactorily explain the spread of infantile paralysis from one part of a city to another, from one town to another, or from one country to another. In this connection, the following theoretical point may be of importance. In a number of instances, it has been noticed that before the beginning of an epidemic, a single case of infantile paralysis has occurred in the early months of the year, perhaps in March or April. The real epidemic, however, has not made its appearance until May or June. In other words, there seems to be a distinct period of latency or incubation, the need of which is hard to determine in view of the fact that abundant susceptible human material is close at hand. The period between generations of rats is approximately three months, and this fact may have some relative bearing: a new generation of young rats possibly being necessary to the further propagation of the disease. Or, perhaps, the virus must undergo a cycle of development in the flea. In this connection may be cited the experiments of Rosenau, who was able to convey to young rabbits the infection of infantile paralysis. The suggestion, therefore, may be pertinent that young rats, like young human beings and young rabbits, are much more susceptible to the disease than adult rats and that in a given epidemic focus, no further progress will be possible until a new generation of young rats has been born. Herein, moreover, may lie the explanation of the fact that epidemics often show two points of maximum intensity a month or two apart.

(NOTE.—Dr. Rosenau tells me that he has been able recently to produce paralytic disease

in rats by inoculation with the virus of infantile paralysis. The experimental data are, however, not sufficiently advanced to justify conclusions.)

8. It has been noted above that districts severely affected by infantile paralysis are rarely affected again for a considerable period of time and that the Swedish observers have attempted to explain this fact by the assumed occurrence of a far-reaching immunization of the general human population. I have already pointed out that such a theory would be tenable only if adults were markedly subject to the disease. I believe, however, that such a local geographical immunization might well be possible through extensive infection affecting primarily not the human but the rodent population. With the immunization of the rats, the human epidemic must necessarily cease. Whether such an immunity exists and can be transferred from adult rodent to offspring must be determined by experiment.

9. In the transfer of the infection from the rat to man, the agency of the flea is assumed, although the possible contamination of food by rodent excretions might well be considered. The insect transfer might be simply mechanical or it might require a preliminary cycle of development of the virus in the flea. Furthermore, the possible rôle of cats, dogs, and other animals, or even human beings, as carriers of infected fleas, would be apparent. Moreover, in grossly unsanitary surroundings, the fleas might carry infection from one child to another directly.

The foregoing theoretical considerations have been put forward as explaining better than any other hypothesis as yet submitted, the epidemiological facts as observed in infantile paralysis.

The human contact theory cannot be made to fit these facts except by efforts so extraordinary that the value of the theory is thereby practically destroyed.

That many and extended experimental investigations will be necessary in order to determine the validity of the rodent theory goes without saying.

Our present knowledge shows the rat to be an enormous burden to mankind from the point of view of both economies and health. If it shall be shown that infantile paralysis is due in any way to the rat, no further argument will be required for world-wide efforts towards the destruction of these vermin.

## SOME MEDICAL ASPECTS OF THE WORKMEN'S COMPENSATION ACT.\*

By FRANCIS D. DONOGHUE, M.D., BOSTON.

*Medical Adviser of the Industrial Accident Board.*

WHEN the Workmen's Compensation Act went into effect in July, 1912, the relation of the

\* Abstract of remarks at the meeting of the Berkshire District Medical Society, June 29, 1916.

medical profession to the treatment of accident cases was considerably changed. The law which went into effect in regard to medical services is as follows:

"During the first two weeks after the injury, the association shall furnish reasonable medical and hospital services, and medicines when they are needed."

The theory of this law was that the insurance companies, who represented the employers of labor, would provide the best kind of treatment, because of the fact that if good treatment was not provided, the period of disability would be prolonged. It is this provision which has made a large part of the so-called dissatisfaction of the medical profession with the Industrial Accident Board, but it is only fair to point out that this is the law of the Commonwealth and is not a rule or regulation of the Industrial Accident Board. Efforts to amend this law and give the injured man the right to name his own doctor, have been made at each session of the Legislature, but without success, and in a recent decision of the Supreme Court, the right of the insurance company to provide treatment is upheld if it offers reasonable and adequate treatment, the only question upon which the Accident Board is called upon to pass. The man is bound to accept it unless he is willing to pay for his own treatment.

The Industrial Accident Board, from the beginning, have been in favor of liberal treatment of the medical profession and a liberal interpretation of the law, so that the man would not only have good treatment but, as far as possible, have the kind of treatment with which he would be best satisfied. To aid in carrying out the law and to try and obtain from the medical profession its support, a largely attended meeting was held at the State House on March 26, 1913, presided over by the Honorable James B. Carroll, the first chairman of the Board, who has since been honored by elevation to the Superior Court and then to the Supreme Bench. The result of that meeting was published by the Accident Board in pamphlet form, Bulletin No. 4, and widely circulated.

Acting upon the advice of the medical profession, the Industrial Accident Board called upon the Massachusetts Medical Society and the Massachusetts Homeopathic Medical Society, each to delegate two members who would serve as members of a committee in conjunction with three men to be appointed by the Board, to pass upon the medical problems from the standpoint of the physician. The result of the meeting of that committee, whose recommendations are contained in Bulletin No. 6, have been followed by the Industrial Accident Board. The recommendations, which are the basis of the decisions made by the Board up to the present time, read as follows:

"Fourth.—That insurance companies be requested to provide suitable blanks for notifica-

tions as well as specifications of services rendered by physicians.

Fifth.—That industrial insurance companies be encouraged to allow all reputable physicians to render services in industrial accidents, provided they are willing to render such services upon reasonable basis.

Sixth.—That the Accident Board should make arrangements with which the insurance companies should cooperate; that any physician whose bill is in dispute may appear before a representative of the Accident Board within a reasonable distance of his home.

Seventh.—That the Accident Board shall provide for medical referees by districts.

Eighth.—That fees paid by the companies should not be less than the average minimum fee in the locality in which the service is rendered.

Ninth.—That charges up to \$50 for major operations are not excessive.

Tenth.—That physicians appearing at hearings before the Board shall receive the compensation as provided for under Section 8, Part III, of the act. (By a subsequent vote of the medical advisory committee this should not apply to the impartial examiners named by the Board.)

Eleventh.—That services rendered by lodge physicians be paid for, provided it is not inconsistent with the rules of the order.

Twelfth.—That specialists, established and recognized by the profession as such, may receive special rates for their work, provided the case requires special skill.

Thirteenth.—That the ruling previously made by the Accident Board, that 'fees should not be charged an injured party whose employer was insured larger than the injured party would be charged were he not insured,' should be interpreted to mean that in a given accident the fee paid by the insurance companies for services should not be less than the average minimum fee for similar services in the locality in which said services are rendered."

In spite of the fact that the law permits insuring companies to provide treatment, the large number of companies permit a free choice of physicians as long as bills are rendered upon what the Industrial Accident Board has termed "an industrial basis." It is evident that both a free choice of physicians, and the payment of all the medical rights of the man to the hands of the insuring company, have elements of weakness which lead to dissatisfaction. The two weeks' period for medical services, worked fairly well, but as there are now risks of 10 months a year that go beyond that period, risks of 10 months were found it would treatment was needed 10 weeks or months after the injury. The Industrial Accident Board passed on to the Legislature of 1913 as follows:

"The Industrial Accident Board requests that the Legislature give the Board the power to require the payment of bills for medical and surgical treatment, medicine, medical and surgical supplies, crutches and apparatus when necessary, beyond the first two weeks after the injury, in unusual cases where the injury is so serious as to require and warrant such additional medical treatment."

Based upon this request, the Legislature passed a law which went into effect on October 1, 1914, amending the law so that the law reads as follows:

"During the first two weeks after the injury, and, if the employee is not immediately incapacitated thereby from earning full wages, then from the time of such incapacity, and in unusual cases, in the discretion of the board, for a longer period, the association shall furnish reasonable medical and hospital services, and medicines when they are needed. Where, in a case of emergency, or for other justifiable cause, a physician other than the one provided by the association is called in to treat the injured employee, the reasonable cost of his services shall be paid by the association, subject to the approval of the Industrial Accident Board. Such approval shall be granted only if the Board finds that there was such justifiable cause and that the charge for the services is reasonable."

Since October 1, 1914, the Board has the right in unusual cases to approve the payment of medical services beyond or after the first two weeks. The unusual feature of each case under the law must be considered and passed upon by the Industrial Accident Board before a doctor is able to collect for services after the first two weeks. The Board, however, has interpreted this, as in all other problems connected with the treatment of an injured man, in a liberal spirit; but for the protection of the doctor and of the patient, application should be made and the insurance company notified before the 14th day when it appears that the case is one that is going beyond the two weeks' period.

The insurance companies in hospital cases where the hospitals have met them half way, have also been liberal, and one type of case, namely, the fractures of the long bone, the fractures of the spine, in which hospital treatment beyond the first two weeks is necessary, have largely been cared for without question. The Board, in addition to taking into account the seriousness of the nature of the injury and the cost of hospital and medical services, takes into account other surroundings of the patient, such as whether or not there are dependents for whom compensation money must be used, and if used for dependents, would leave little for medical care. In other words, the amount of compensation paid and the demands made upon the compensation are both factors which should be represented to the Accident Board when applications are made for medical treatment.

Under the first law, the doctor had no individual standing in regard to the collection of his bill. He could not ask for a hearing and his rights to collect were so merged with the rights of the injured employee, that unless the injured employee asked for a hearing upon the doctor's bill, there was no way for the doctor to get a hearing. The Industrial Accident Board petitioned the Legislature that this be remedied. The Legislature passed a law which went into effect on June 25, 1914, amending the law so that the law reads as follows: (Section 13, Part III.)

"Fees of attorneys and physicians, and charges of hospitals for services under this act, shall be subject to the approval of the Industrial Accident Board. If the association and any physician or hospital, or the employee and any attorney, fail to reach an agreement as to the amount to be paid for such services, either party may notify the Board, which may thereupon call for the formation of a committee of arbitration, in accordance with the provisions of this act, and all proceedings thereunder shall be in accordance with the provisions of this act."

The Workmen's Compensation Act has, as a fundamental, the insurance of the wage-earning capacity of the worker and not the insurance of the employer against lawsuits. If the law is approached with this idea in mind, it would at once appear that the restoration of function, if accidents cannot be prevented, is of almost paramount importance. Restoration of the worker means prompt and adequate care that dangers to life may be minimized, that long disabilities be prevented, and that when healing processes are complete, there shall be treatment and training given so that the injured may use, to the best advantage, the mutilated or disabled part which results from his industrial injury.

Among other things in the interpretation of the law, the Board has interpreted, as medical services, dentistry; but dentistry, when needed, should only be provided after consultation either with the insurance company or the Board. Eye-glasses have been considered necessary for the restoration of men to work; artificial eyes have been provided and, by agreement with the companies, artificial limbs also.

The old method of determining the rights of an injured man, based upon his one day in court, under the Workmen's Compensation Act, is greatly changed. Opinion evidence, therefore, as to diagnosis and prognosis, does not have the same relation to the rights of the man that it does in ordinary court procedure.

In the first place, it is necessary to determine if the injury arises out of and in consequence of the employment. That settled, the next important thing is to give such treatment as will restore the injured employee to his former wage-

earning condition. In the hearings before the Board, there is not the effort to settle the case at one hearing, that always is made in a court of law, but he is entitled to observation under competent medical observers acting impartially for the Board, and over a sufficient period of time, so as to insure proper consideration of the injured man's rights from all standpoints.

The wage earner of the Commonwealth is one of our greatest assets and the loss of time of any trained workman is a loss not only to himself, but a loss to the community. One of the first results of the Workmen's Compensation law, aside from the applied Christianity which is involved, is the fact that the workmen receive adequate care in the form of medical services, but what may be more important, a study is made to prevent the occurrence of accidents; and prevention is undoubtedly better than compensation.

A large part of the criticism of the Industrial Accident Board from the medical profession has come, I think, from not understanding what the Accident Board can do and what the Accident Board cannot do. The Industrial Accident Board is created by a law which carefully defines its powers, and it also defines certain procedures which the Industrial Accident Board is bound to follow. Just as the Workmen's Compensation law altered materially the relation between employer and employee, so it altered the relation of the medical profession to injured employees. It also altered the relation of the lawyer and his client, if the client was an employee insured under the Act. To pass upon the rights of the employer represented by one of the many insuring companies, the employee, the hospital or the doctor who cared for the employee, the lawyer who looked after his interests, are a part of the duties of the Industrial Accident Board.

There is a considerable misunderstanding about the functions of the medical adviser of the Industrial Accident Board and he is criticized for many things about which he knows nothing and for which he is in no way responsible. If you will pardon me,—because this is rather personal,—I would like to say that under the law the medical adviser is adviser to the Industrial Accident Board on such matters as they ask his opinion. His opinion is not taken as a substitute for other testimony given at hearings, unless he appears in the case and testifies under oath. For that reason, medical testimony given by the attending physicians, or others called in cases, should be given with as much thought and care as if given in any other court, because the committee of arbitration under the law has no other evidence on which to make findings and it is only on review or appeal to the full Board that other evidence may be introduced. The medical opinion on a given case is important if properly considered, but it

does not supplant testimony in regard to facts which are presented by other witnesses.

The law is not perfect; it is in process of change, but it has, as a fundamental, the proper conservation of the wage earner and offers a great field for medical study, medical investigation and constructive medical care.

To carry out the law, the Industrial Accident Board must depend upon the medical profession both for proper treatment and to see that the attention of the injured workman is properly called to his medical rights when the right depends upon some fact of which only the medical profession would have proper knowledge. It must depend upon the profession for certificates regarding the condition of men, and must rely upon their testimony in arriving at just conclusions. There is a great obligation on the profession to aid in carrying out this most humanitarian act.

## THE WEASEL IN MEDICINE.

MR. PHILLIP HALE has recently called attention to the description given in Edward Topsel's "History of Four-Footed Beasts and Serpents" (London, 1658) of the medicinal uses that were made of the weasel in the spacious Elizabethan days and thereafter, as late as the Restoration. The following is the remedy recommended for gout:

"Take a little young whelp alive, well fattened, and a living Weasel in nine pints of Oyl, and unto the same two or three pounds of butter and boyl them together until the beasts be made lank or lither, and then put your hands or feet a whole day in hot Oyl well strained." It would be easier, continues Mr. Hale, to put weasel powder in wine; this would also be efficacious in epilepsy, the headache, and in case you were bitten by a scorpion; also for palsy or shaking of the joints; "very effectual for the expelling or taking away of the pain and welo of the eyes"; it helps all sores and impostumes. Some recommend the brains of a eam I mingled with those of a weasel. If an ox or horse is stung or bitten, stroke the wounded place with a weasel skin. If you are bitten by a weasel, apply onions and garlic externally, or a sweet wine.

"Two remedies should here be given. The powder of a weasel being mingled with the blood of a young swallow cured the rabies or spinnzie. The same is also very effectual for the expelling of wens or cancers in the body. The same diseases are cured by a decoction of wine, to burn a young weasel, cut together in earthen pot, and to mingle with the powder thereof Honey, Turpentine and Butter, and a sufficient quantity of oil, and the same may be

Ointment to apply it unto the bodies of the grieved parties."

"There is a speedy remedy for the driving away of rheum in the head, and the Catarrh swelling by rheum in the jawes, which is this: To take a Weasel upon a Thursday in the old Moon, and put him alive in an unburned pot, that in the Boyling he may be torn, and dried into powder, which powder being gathered together and well tempered with Honey, to give it to the diseased person every day in a spoon fasting, to the quantity of three drams, and it will in short space wonderfully ease him."

"These remedies, Mr. Hale pertinently observes, were prescribed by the wisest ancients. They were soberly advised in 1658. What will men and women of 2158 say to the treatments and prescriptions of 1916?"

## THE MAJOR DIVISIONS OF MENTAL HYGIENE—PUBLIC, SOCIAL, INDIVIDUAL.\*

By E. E. SOUTHAARD, M.D., BOSTON.

*Director, Psychopathic Hospital, Boston.*

I TOOK occasion in preparation for this discussion to jot down a number of points which I might desire to make concerning mental hygiene. To my astonishment, I shortly found that I had written out no less than seventy-nine headings. These I shall forbear to present to you in their fulness, and hope that the chairman will call me to order when the fatigue point of the audience is reached.

It is unlikely that there should be seventy-nine main divisions in mental hygiene. The classical situation with numerous sciences and arts is that they shall divide up into three or perhaps into five divisions. As a fact, I found very many of the considerations in mental hygiene may be grouped under three headings. There is a *mental hygiene of a public or governmental nature*; there is a *mental hygiene of a social nature*; and there is the far more familiar and well-known *mental hygiene which considers the individual* as such. Dean Pound of the Harvard Law School has divided legal interests into public, social, and individual, and I feel that his legal distinction pretty well holds in mental hygiene.

If we run through the great group of admissions at a hospital like the Psychopathic Hospital (which this year, 1915, has admitted no less than 2000 patients), we shall find that a certain large proportion of the cases are routine cases,

whose public, social, and individual features are obvious and clear, immediately suggesting an appropriate disposition and appropriate measures of treatment. These *routine* cases may not all be successfully treated from the standpoint of the individual; but from the standpoint of society and the public authorities, they can be successfully handled on the basis of familiar and well-understood rules of government, society, and medicine. But over against these routine cases, we find a minority of cases of a more difficult nature, which I may call the *intensive* group. The physicians among you will call to mind at once cases of mental complications in pregnancy, cases of brain syphilis requiring special treatment, and the like. It is true that these cases form an important subgroup among the intensive cases and require expert examinations and special devices in treatment. But aside from these intensive medical cases, we find once more that the public, social, and the individual grouping, which I have just mentioned, is further exemplified. For instance, we find a small but perturbing group of (a) public service cases. In this group, we have to deal with cases of family dispute with respect to will making and the like. Again we have to deal with superior court cases given to us for medical examination and decision. Again the police courts and the juvenile courts give us cases of such a special nature that they belong in the intensive group. The Industrial Accident Board and the Immigration Service, to say nothing of the schools, furnish their quota.

Besides the public service group, there is what may be called (b) a social service group of cases, in which legal problems are not prominent, but in which economic and domestic, and other environmental difficulties predominate. Again, we have a great number of (c) individual cases which are neither intensively medical nor of particular importance to the public authorities from the standpoint of community welfare, nor again of particular social importance or open to social service management for their cure or amelioration.

This brief characterization will serve to indicate some of the main divisions of mental hygiene as they develop, from a review of cases actually flowing into such an institution as the Psychopathic Hospital. You are, doubtless, all aware how different in its scope and effect the Psychopathic Hospital is from the ordinary hospitals for the committed insane. Our cases are a group that in former years would never have reached the hospitals for the insane, at least in any such quantity. So much I would say to a lay audience by way of emphasizing the fact that the task of mental hygiene is not merely that of improving the outlook of the given individual. From Feuchterleben's work on the "hygiene of the soul," to date, it is true that mental hygiene has developed from an interest in the individual, and I for one am not disposed

\* Read before the Conference of the Massachusetts Society for Mental Hygiene, Ford Hall, Boston, Nov. 17, 1915.

to regard this, in some sense, narrow view of the function of mental hygiene, as at all unfortunate. Many of the most effective workers in the mental hygiene movement have started from an entirely individual interest in the problem, seeking the way out at first by endeavors to legislate improvement into the situation, and later by the slower process of moulding public and social opinion. But to deal with mental hygiene in any of its phases means that we are carried directly from the problems of the individual to problems of society, and if life favors us with a little power, our interests pass from the less definitely social range to that more definitely crystallized portion of society's efforts known as government. In short, no one interested in the mental hygiene of the individual but finds himself forthwith launched upon one of the most stimulating of all social uplift movements, leading directly to efforts to establish in the framework of government a variety of measures for the mentally sick and defective.

The laity and the medical profession need no warning about the value of individuality in every human being. We do find, however—I speak possibly as a somewhat prejudiced physician—that the legal profession and the courts fall prey to a certain formulating tendency in which the interest of the individual gets lost or obscured. One of our problems in mental hygiene is to force the necessity of individualization of diagnosis and treatment upon the legal profession and the courts. I do not refer merely to the lack of individual handling of criminals and alleged criminals, although the situation here obviously enough calls for a revamping of the legal point of view. You will all have read or gotten some inkling of the work of Healy on the Individual Delinquent. As a medical man, I was struck with the vehemence and insistence of Healy's claim for individualization in the classification and handling of delinquents. Medical men and thoughtful laymen do not perhaps need to be brought to look upon what they regard as so obvious a matter, namely, that each human being, whether or not alleged to be a criminal, requires individualized management. If we look into the criminological world, however, we shall find that the lawyers and the judges, and perhaps even some probation officers, need to go a good way before they will arrive at what medical men would regard as a proper individualization of their material. This is doubtless why Dr. Healy, fresh from his rich experience on the border line between medicine and law, should have thought fit to devote a large work like *The Individual Delinquent* to the necessity of individualization in the handling of medical aspects of delinquents.

I said awhile since that individualized handling of mental situations by the lawyers and the judges should not be confined to criminals and alleged criminals. It is our task to demonstrate to the lawyers and the judges that the concept

insanity itself is a somewhat artificial unit; that in point of fact, every insane person is really the victim of a particular form of mental disease. Kraepelin remarks that one should hesitate to classify a person as insane unless one can put him in a particular disease group. It is a question how far any but the most enlightened judges and lawyers understand the nature of the point I am endeavoring to make. The crystallized form of social service which we call court procedure or a system of jurisprudence is from its very nature liable to overformulation. The rock upon which social progress is founded is consideration for the individual. We must convince our servants in that more crystallized, not to say fossilized, regions of social service called public service, in the first place, that it is not government they are serving, but society; and that in the end, it is not even society which is so important as its individual constituents,—men and women.

The social workers of the audience will be inclined at this point to pick a quarrel with me, for they are aware that physicians are by no means always ready to take that kind of interest in the individual as such as is ingrained in the hearts of social workers. The social workers find that we physicians are more interested in *parts* of individuals than in the individuals themselves. They respect our analyses and want our diagnoses; but between the analytical physicians, on the one hand, and the overformulating governmental representatives on the other, the social workers find a heavy task. Administrators tell me that social workers often strive to break the law gently for the purpose of helping individuals. Physicians tell me, on the other hand, that social workers may easily have too much confidence in the ability of money and vacations to solve medical problems. The social worker is, in a sense, the marrow of the present situation. I believe that a prominent practical sociologist has questioned whether social work at this time is a profession. If not, social work is at any rate a sort of cement substance or intermediary body between all the various agencies which I have mentioned, to say nothing of the hospitals and relief agencies. Social workers carry the decision of the physician to the lawyer, the decision of the lawyer to the physician, and the decisions of both to the family. They may even be found explaining these decisions to the patient himself, sometimes a doubtful expedient in the case of psychopathic persons, and they carry the news from the individual to his family, from the family to the judge, to the probation officer, to the physician, and to the public administrator or administrator.

The major disservice that is being done to society from the present aspect of the individualization of social, and as a corollary, the individualization of the public branch of mental hygiene, is the placing of the hands of the lawyers and the judges upon the

ministrators, upon whose experience judicial decisions and statutory provisions will gradually develop the power of society over the psychopath and his family, not only in the interest of society and the family, but also in the interest of the patient himself. The non-public, or more broadly *social branch* of mental hygiene is still in an unfinished and developmental state owing to the doubt which prevails whether social service is as yet a profession. Until it becomes such, doubtless no great amount of leverage can be got for improvement of the social situation on behalf either of the psychopath or of his fellows. In point of fact, evolution in the past has tended in some countries to make public duty out of every well demonstrated social need. Social workers should not be sorry if their tasks are removed from them as soon as they begin to be successfully performed. As for the *individual branch* of mental hygiene, there has been, as is well known, a great increase of interest in the individual as an individual, derived largely from French, and later German, efforts in psychopathology. The analytical pathologist who sees his subject segregated into a lot of interesting items is being replaced with a more synthetic type of physician who sees the individual as such. Curiously enough, one of the most striking signs of this development is in a movement called psychoanalysis. The leaders of this movement are far less analytic in one sense than the routine examiners whom they wish to replace. The psychoanalysts are almost from the beginning of their labors synthetic. They put two and two together almost at the outset of their examinations and constantly see the individual as such. Whatever be the truth as to psychoanalysis, it is certain that the movement itself is but one symptom of the wave of individualization which is passing through a great many sciences and arts.

I might say much concerning the technique of mental hygiene. I might insist upon the value of getting a large and increasing number of persons to resort voluntarily to public institutions for examination; or endeavor, in the words of one critic, to make mental disease in a sense fashionable, as it has been claimed nervous prostration is fashionable. Parenthetically, it is of course true that nervous prostration is in a great many cases a mild, or even relatively severe, psychosis, and is merely termed nervous to escape the suggestions of the term "mental."

I might insist also upon the importance of stimulating the temporary care of cases not subject to court review and thus acclaim the modern tendency to take mental cases under medical care much as ordinary medical cases are taken.

I might further enlarge upon a division of the tasks of mental hygiene into a task of prophylaxis and a task of after-care; but for this time does not now permit, and all these important matters of voluntary and temporary care

admissions, of the prophylactic and after-care divisions of mental hygiene, have been or will be sufficiently brought before the audiences of this conference. Other features of the general situation, such as the great value of work with alcoholics and the salvage process as applied even to apparently hopeless victims of delirium tremens, should obtain a hearing in any proper presentation of the subject of mental hygiene. The new syphilis programme dependent upon an increasing number of important medical observations and discoveries in the past few years, is also worthy of special attention. Into these things I shall not at present go, and I shall consider my task sufficiently well executed if I can go home satisfied that my contentions about individualized classification, diagnosis, treatment, and management of all cases, whether or not they belong to the medical man chiefly, to the social worker, or to the public authority, are deemed worthy.

#### WHAT RECENT INVESTIGATIONS HAVE SHOWN TO BE THE RELATION BETWEEN MENTAL DEFECT AND CRIME.\*

BY A. WARREN STEARNS, M.D., BOSTON.

*Special Investigator, Massachusetts State Board of Insanity.*

ALTHOUGH the word "defect" appears in the title announced for my paper, and thus would seem to limit the scope of my remarks, I think it best to consider in my discussion not alone the relationship of mental defect to crime, but the relationship of mental disease in general to crime.

When one looks over the literature of the last few years about crime and about mental disease, it is surprising to see how well understood the relationship between crime and mental disease appears to have been for some time. It is also surprising, or at least it leads one to wonder, why so little has been done. Recent investigations have only proven apparently what we have known for a long time. The chances are—perhaps more formerly than now, but even now—that of all persons going to hospitals for the insane, anti-social or asocial conduct is a factor in a large majority. It is either anti-social conduct or fear of the possibility of such that leads most people to consider the state hospital. It is also a fact, I think, that every person who is called a criminal is now thought to have some mental variation from the normal. That variation may be slight, of course, but while it seems only too obvious, it is necessary to insist upon some attention being paid to this relation.

\* Read at the Conference of the Massachusetts Society for Mental Hygiene, Ford Hall, Boston, Nov. 18, 1915.

To-night I want to sum up what has already been demonstrated under our very eyes here in Massachusetts. At the recent Conference of Charities in Pittsfield, there was some comment about the fact that the Massachusetts man takes Massachusetts as all-sufficient. I do not confine my remarks to Massachusetts in any such belief. I merely do it to show that under our very eyes enough has been done to warrant active steps being taken to correct an apparent neglect. I shall run briefly over the work of several persons, and having thus boldly asserted that there is a marked relation between mental disease and crime, I shall attempt to prove it by citing Massachusetts, and, for that reason, familiar authorities.

The first name which one strikes in considering this topic—the first work, at least—is that of Dr. Walter E. Fernald,<sup>1</sup> of Waverley. Dr. Fernald tells me that when he first started talking upon the relation of crime and mental disease, a newspaper editorial said that he had been looking at imbeciles for so many years that he saw them wherever he looked. At any rate, Dr. Fernald has been in a position to study the question and to demonstrate the relationship between the two social problems. He also first called attention to the fact that the criminal man described by Lombroso was none other than our imbecile boy.

The next work which has impressed me as being especially important is that of Dr. Henry R. Stedman,<sup>2</sup> who has been a pioneer in getting helpful legislation. Massachusetts has had some very wise laws for many years; laws by which any judge has authority to ascertain the mental condition of any prisoner; laws by which the judge has the authority to commit such a prisoner to a hospital for observation. Massachusetts was a pioneer in this direction, but unfortunately these laws have not been used as much as one would like.<sup>3</sup> Of seven or eight hundred patients at the Hospital for Criminal Insane at Bridgewater, only about one-seventh were sent there by operation of these laws. The other six-sevenths were sent there because these laws were *not* used and a roundabout method had to be employed.

Some years ago the Concord Reformatory recognized the need of expert advice, and employed Dr. Guy Fernald<sup>4</sup> as their prison physician. The conservative, concise reports which he has made from time to time of conditions there, when one considers the almost opposite reports which we have had from other sources, giving percentages of from 1 to 100%, are most welcome. It is refreshing to find a man who has consistently kept his eye to the ordinary, and given sensible results which everyone could grasp. Dr. Fernald, in his latest papers, states that 15% of the boys at Concord should be segregated because of their mental condition.

Somewhat later, under the stimulating influence of Mrs. Jessie D. Hodder at Sherborn, Dr.

Edith R. Spaulding began a similar work dealing with another sex, and in a way another class of dependents. She reports that 24% of the reformatory population should be segregated because of their mental condition, and that nearly half of the population show some degree of mental defect.

Next, and quite recently, Judge Bolster at the Central Court has succeeded in employing Dr. Victor V. Anderson<sup>5</sup> to make a beginning there. Dr. Anderson has not had an opportunity to get sweeping statistics, but in his first report, 30% of 100 sent him for examination were found to be feeble-minded, which shows that they are there, as elsewhere.

Still more recently, the Massachusetts State Board of Insanity has conducted three investigations looking toward the segregation of those now in the wrong institutions.

The first of these dealt with the class called "defective delinquents." It demonstrated that in our state hospital population, there is a considerable number—mostly girls—who are not definitely insane, not definitely feeble-minded, but whose conduct it is difficult to control. Their advice was that there should be a separate department or institution for such dependents.

The next investigation dealt with the population of the Bridgewater State Farm. That showed several things. In the first place it showed that obvious cases of insanity were being sentenced as criminals. It showed that the long drawn out examinations which one thinks of as mental examinations would not have been necessary in at least one-third of those cases. The ordinary judge or probation officer should have had training enough to have recognized in at least one-third of those cases that the trouble was mental disease or defect.

The last investigation of the Board of Insanity dealt with the population at the State Prison at Charlestown,<sup>6</sup> and as far as that has gone it also establishes the relation between mental disease and crime. Nearly one-fourth of those examined showed a considerable degree of mental defect. In each year's admissions, of 125 to 175, 15 to 20 are transferred from Charlestown to Bridgewater, as insane.

Having thus established the relationship between crime and mental disease, one might well ask what is to be done about it. There are about 176,000 arrests in Massachusetts a year. Obviously it would not be possible to do everything that can be done by way of arresting each of that number. It would take hundreds of physicians and require months of work. And it would not be practicable at present. My belief is that the first mental examinations should be made by probation officers, judges at police officers. If that were an advance to be made, or feeble-minded, or even mildly insane, we would weed out of our criminal class a step which has been taken with regard to mental defect. A change in statistics is important. I believe that

cite cases at a meeting of this sort, and I think I had better not do it; I will simply say that numerous cases have come under observation where, following 10, 12 or 15 years of hospital residence, insane persons have been within a few days after their escape sentenced as vagrants. Known inmates of the school for the feeble-minded have been arrested, their defect ignored, and sentences imposed.

I think that there is some responsibility which is not being fulfilled by our courts in picking out these known insane and feeble-minded. I think that an examination several hours long is not feasible or necessary. I think that a good history of the life, brief and easy to get from every man arrested, obtained before sentence, would in the majority of cases enable a non-medical man to separate out most of the insane and feeble-minded. In other words, rather than a new law, there is needed a better understanding and working out of those already in existence.

I think we need to focus our attention upon these facts, which are now very well known, and instill the spirit of investigation rather than that of precedent into the courts. I believe that responsibility as well as power is at present in the courts.

## EPILEPSY.\*

By EVERETT FLOOD, M.D.,

Superintendent, Monson State Hospital.

A DEFINITION of epilepsy is difficult. The root meaning of the word conveys very little idea of the condition, but it has come to have the applied meaning which seems to be all that is necessary. If a person has a fit of any degree,

mild or severe, frequent or infrequent, and this fit is repeated even a few times at intervals, we say that the person is epileptic; but it ought to be understood that epilepsy is not a disease. It is a symptom, or a collection of symptoms, of quite a variety of conditions.

It is probable that among the people of civilized countries there may be found at least three persons in every thousand who permanently have recognized attacks of epilepsy. It is also true that a very large number never come to light, and that the person afflicted goes on through life with real epilepsy but is never counted among the epileptic class. In the whole community, about one child in twelve has some sort of a fit in early life. A few have them repeated, and yet nearly all fail to become epileptic. Mothers are not worried as to the future when the baby has a fit.

The problems connected with the institutional care of epileptics are very much the same problems as those connected with the care of the feeble-minded and insane. In 500 cases of feeble-minded, 11% are epileptic. This 11% are essentially like the balance that do not have fits. They do not even rapidly go down hill mentally during a long series of years. Those epileptics who do become come from the classes not so primarily feeble-minded.

Of the institutional cases which come to autopsy, 78% show gross brain lesions. Probably nearly all the other cases show microscopic lesions. There is no way of knowing whether there are actual lesions in the cases of those who as a rule do not come to institutional care, and this class is very much larger than the class that does come to institution care.

A person who is afflicted with epilepsy may be engaged in any occupation, but if his attacks recur many times, he is sure to lose his position; and I doubt if there is often a case where the epileptic symptom is at all prominent without some manifestation in conduct which is different from the absolutely normal.

Of institution cases, 184 epileptic children were examined with great care. Fifty-three per cent. of these were distinctly feeble-minded; 44% were on the road to dementia; 2% only were without very positive mental symptoms. Among 1033 cases, including the 184 young persons cited above, 631 are feeble-minded, 377 insane, and 25 normal. All the normal but two are among the children.

In a group of 221 cases, 30% presented active mental symptoms such as mania, delusions, and hallucinations. This agrees somewhat with the 44% who finally become.

When we find that so many of the cases in which epilepsy occurs are among those who are defective, it is natural to assign this enfeebled mental condition as in some way a cause of their epilepsy. How this occurs in a few of the feeble-minded, and in a majority does not, I think would be impossible to say. We may as-

\* Read before the Conference of the Massachusetts Society for Mental Hygiene, Ford Hall, Boston, Nov. 19, 1915.

sume that there is some inherited tendency which produces this epileptic symptom, and this seems to be as far as we can venture.

A large number of cases of epilepsy have an inheritance of either feeble-mindedness, epilepsy, migraine, alcohol, or insanity.

A certain number of cases of epilepsy are of course caused by injuries to the head, and some follow such conditions as scarlet fever and measles, but it seems almost necessary in these cases to assume a predisposing cause, as an immense number of head injuries and scarlet fever attacks are not followed by epilepsy.

If parents can know the tendency to epilepsy, or the liability of a certain condition coming about, they can care for their children, provided they have the proper intelligence and suitable surroundings, and so guard the child in the way of wholesomeness of living, diet, self-restraint, etc., as to tide them over the critical periods of childhood to maturity without their manifesting this symptom. This has apparently been done in many cases, and parents should certainly be taught how to take care of children who are especially liable. After the fit has once occurred, the matter is one of difficulty: if it occurs at intervals for quite a number of times, then it is one of extreme difficulty. However, even then it is not hopeless in all cases and very much can be done in the way of home care, which is superior to institutional care, if properly conducted. When it comes to be a question of isolation for the prevention of sex difficulties, of course, the comparison between home and institutional care is on a different footing.

## IDIOSYNCRASY TO COW'S MILK; ITS RELATION TO ANAPHYLAXIS.\*

By FRITZ B. TALBOT, M.D., BOSTON.

*Chief of Children's Medical Department, Massachusetts General Hospital; Instructor in Pediatrics, Harvard Medical School.*

THE condition described as an idiosyncrasy to cow's milk may manifest itself with some or all of the following symptoms: When an infant is given cow's milk, even in small amounts, it vomits almost immediately. This may be followed by mild or severe diarrhea, high fever, or more commonly, a subnormal temperature, weak pulse, and other symptoms of shock. In a few cases convulsions, spasm of the glottis<sup>1</sup> or an urticarial rash has been noted. These symptoms may occur when cow's milk has been given for the first time, or after the second or third bottle, especially if breast milk has been given between the bottles. The pronounced idiosyncrasy to cow's milk, which is the subject of this communication, is relatively rare.<sup>2</sup>

It has been shown that the gastro-intestinal wall of the newborn infant is permeable to a foreign protein,<sup>3</sup> and that soon after birth an infant develops the power of destroying the foreign protein, digesting it in such a manner that when it reaches the blood stream, the foreign element is absent. This may be brought about in two ways:

1. By digesting the protein down to amino acids, and during the process of digestion, removing the foreign element from it, or
2. By developing antibodies, which will destroy the foreign element in the protein as it passes through the intestinal wall.

Certain individuals, whose parents and close relatives give a history of such anaphylactic phenomena as asthma, hay fever, chronic urticaria, or idiosyncrasies to foods, have a hereditary predisposition to sensitization. Hyashi<sup>4</sup> attempted to determine the tolerance of twenty-eight normal infants for egg albumen, and found that infants with the "exudative diathesis," or those who had recently recovered from acute disturbances of digestion, had a lower tolerance for egg than normal infants.

After the body has developed its protective functions, injury to the intestinal mucous membrane is necessary for the foreign protein to pass unchanged through the intestinal wall directly into the blood. Such injury may accompany acute indigestion, infectious diarrhea, or any mechanical injury to the intestinal mucous membrane. Moro<sup>5</sup> has shown that a small proportion of babies (two out of twenty-one), with disturbances of digestion, had precipitins to cow casein, in their serum. Lust,<sup>6</sup> Hahn,<sup>7</sup> and Modigliani and Benini<sup>8</sup> brought forward further evidence for the permeability of the intestinal mucous membrane to foreign protein, and obtained a larger proportion of positive results than Moro. Many experiments on animals have shown that it is possible to sensitize animals to foreign proteins through the digestive canal.<sup>9</sup> Sensitization can be brought about by feeding either raw or boiled milk. It is more difficult to sensitize guinea pigs with milk boiled fifteen minutes, and they cannot be sensitized by milk which is inactivated by passage through a Berkefeld filter.<sup>10</sup>

It is necessary in certain instances to specify the doses of the foreign protein as to sensitivity and not immunize the individual. Just as when a laboratory animal has its dose of foreign protein given to it at stated intervals during the process of sensitization, so must the foreign protein in the case of the baby, even when he is given to the infant. The first time when a baby was given a bottle of cow's milk and once in ten days. In other instances the first cow's milk, and all subsequent bottles, were given to the baby, and in some instances, in which case we must assume that the sensitization was hereditary and present at birth.

\* Read before the New England Pediatric Society, April 25, 1916.

If, on the other hand, cow's milk is given daily, a natural immunity ought to develop, just as it does in the laboratory animal. The work of Schloss<sup>11</sup> and Berger<sup>12</sup> gives very suggestive evidence by differential counts of the white cells in the blood, in favor of this view.

The following cases are examples of idiosyncrasy to cow's milk:

CASE 1. D. T. A healthy baby which had always been breast-fed until he was eight and a half months old, when he was given one bottle consisting of whole milk, six ounces, and barley water, two ounces, because the mother's milk was giving out. This was not given again until three weeks later, because the baby had a middle ear. After he had recovered, whole milk, seven ounces, and barley water, one ounce, was tried and refused by the baby. It was, therefore, spooned into him, and he vomited it almost immediately. Whole milk was then omitted and whey tried, with the same result. One week later one ounce of a mixture consisting of whole milk three ounces, cane sugar three level teaspoonsful and boiled water five ounces, was vomited. He was then given the breast and cereal gruel only, and did well for one week, at the end of which time one ounce of milk was put into eight ounces of cereal gruel, and a teaspoon of this mixture given. The baby "shuddered when he swallowed it," vomited shortly afterwards, and within an hour his body was covered with an urticarial eruption. It was then certain that he had an idiosyncrasy to cow's milk. (The shuddering is a characteristic symptom in these cases.) The milk of a goat was then obtained, and was taken without any symptoms or further trouble. Six months later, November, 1914, cow's milk was given to him without any ill effects, and he has been taking it ever since.

CASE 2. A. P. A girl of 17 months of age, with the following history: She was the first child of healthy parents, born at full term, Caesarean section, weighing five pounds at birth. Her mother was unable to nurse her, and during the first eight weeks of life she was given modifications of cow's milk, most of which were vomited. She lost weight, had undigested stools, and did not sleep as a normal baby should. At nine weeks of age she was put on a wet nurse and has had breast milk ever since. At six different times, attempts were made to wean her and she was given cow's milk in various ways, as condensed milk, whey, and in all sorts of modifications, but in every instance the milk was vomited, and the baby became very ill. She was limp, pale and cold with profound shock. These attacks were never associated with urticaria. Once when Mellin's food and milk were given, the baby "almost died." The physical examination showed a pale, poorly developed and nourished baby, weighing 15½ pounds. Aside from a general lack of development, the physical examination was normal. Scarification skin tests were done with the following materials—fresh cow's milk and dried cow casein, the protein of barley and potato,<sup>13</sup> all of which gave slight positive reactions. These positive reactions were narrow, elevated, urticarial wheals, surrounded by a slight reddening, while the control scarification, and that to which egg was

applied, showed no reddening or elevation, and were, therefore, negative. The baby was then given goat's milk which it took without any symptoms, and was entirely weaned in two weeks' time. The mother reported one and a half months later that the baby was doing well and gaining in every way on the goat's milk.

Since the skin test to cow casein and fresh cow's milk was positive, this was a case of anaphylaxis to cow's milk. When goat's milk was given in these two cases it did not cause any symptoms. This was because the anaphylactic element in the food was not due to the milk itself, but to the cow in the protein of the milk. Mare's milk, probably, would have done equally well since it was the milk of another species. The writer does not claim any originality in the use of goat's milk in these cases, since Barbier<sup>14</sup> used it in 1910. He feels, nevertheless, that it has a definite indication for use, and that it should be used in all cases of idiosyncrasy to cow's milk.

#### CONCLUSIONS.

1. Foreign proteins may pass through the intestinal wall of infants shortly after birth, and in later infancy, when the mucous membranes are injured.
2. Idiosyncrasy to cow's milk is an anaphylactic phenomenon and can be demonstrated, at least in some instances, by a specific skin test.
3. The treatment consists in giving the infant milk from another species of animal, preferably that of the goat.<sup>15</sup>

## Therapeutic and Preventive Medicine.

### TREATMENT OF TUBERCULOSIS IN INFANCY.\*

By WILLIAM W. HOWELL, M.D., BOSTON,

*Associate Physician, Infants' Hospital; Assistant in Pediatrics, Harvard Medical School, Boston.*

THE diagnosis of chronic or acute tuberculosis was made in 12% of 600 consecutive medical cases under two years of age admitted to the Infants' Hospital after March, 1914. The admitting diagnoses were pyelitis, obscure fever, anemia from various causes, chronic indigestion from fat or overfeeding, bronchitis, acute indigestion with fermentation, infectious diarrhea, tuberculous meningitis; and a few were admitted for observation. Tuberculosis had not been recognized in any of the cases except the acute ones with meningitis.

I think the general impression is that tuberculosis in infancy, though a preventable disease, is hopeless, incurable, and not to be permanently helped by treatment. I think this impression and failure to recognize the disease come largely from a difference in opinion as to what constitutes tuberculosis in infancy, and before discussing the treatment it will be necessary to define clearly what is meant by the term tuberculosis in infancy.

We often hear the question debated as to what constitutes tuberculosis in infancy, but I cannot see what difference it makes whether it is infantile or adult tuberculosis. What constitutes tuberculosis is infection with the bacillus of tuberculosis, and when infection takes place, there results a pathological process whose nature has led to all the discussion as to whether an infant has a disease of tuberculosis, or is merely infected with tuberculosis. It is very dangerous to try to make such a distinction, for if the bacilli have gained entrance into an individual, they have set up a process which is permanent, which in infancy gives symptoms and is kept active enough to have living bacilli in it, and is a constant menace to health. Another dangerous expression, fortunately little used now, is "pretubercular stage," a sort of threatened-with-tuberculosis idea—as if there could be a disease with symptoms in any way connected to that disease before infection with the contagium of that disease had taken place.

I think it is now pretty generally accepted that tuberculosis is similar to syphilis and leprosy in that it is a disease with a primary lesion. The bacilli gain entrance through the tonsil, lung, intestine, skin or wherever the portal of entry may be. There may or may not be a permanent lesion at the portal of entry, but the lymph glands draining the entrance point become inflamed and enlarged. If the portal of

entry is in the lung, the primary lesion is usually demonstrable in the lung tissue as a grayish nodule in size from the head of a pin to a split pea, with the glands at the hilus of the lung on that side much enlarged. The primary focus is not always found in other localities. This constitutes the primary lesion, the primary focus and the enlarged glands; the primary focus may not be found, but the glands remain chronically inflamed with living bacilli in them. It is the primary lesion with its glands which is referred to when it is said that an infant is infected with tuberculosis, but has not the disease of tuberculosis. What is meant, however, is that the infant has none of the signs in his lungs or anywhere else which have long been taught to be the signs of tuberculosis. This condition is diagnosed at the Infants' Hospital as chronic tuberculosis to distinguish it from all other forms of tuberculosis resulting from secondary changes in the primary lesion, or from reinfection from without. These secondary changes result from extension by contiguity from the primary lesion, from breaking down of the primary glands and discharge of bacilli into the lymph or blood streams, or into the digestive tract by sputum. Secondary forms may also result from repeated reinfection from without. These secondary forms are diagnosed as acute tuberculosis, hence we have the primary glandular tuberculosis as chronic tuberculosis and the secondary forms as acute tuberculosis.

Now after this hasty summary as to what tuberculosis in infancy means, I think we may consider the treatment. If as tuberculosis in infancy, only those cases are recognized as such which give physical signs and symptoms of the secondary forms, that is, tuberculous meningitis, tuberculous bronchopneumonia, peritonitis, and so on, then there is little or nothing to be said about treatment, for there is nothing to be done except to make the baby comfortable. They all die, except a rare case of tuberculous bronchopneumonia or peritonitis. However, all secondary cases should have as near absolute quiet as possible, sufficient food but not to overtax the digestion, and fresh air but not necessarily cold air, in order to save every bit of energy, hoping that the disease may be arrested.

The first step in the treatment of infantile tuberculosis is to be willing to accept the primary lesion and all that it means, and to forget the term infected with tuberculosis as indicating the disease of tuberculosis. The fact that a primary lesion does not have symptoms is referred directly to the location of the lesion involved. When local symptoms are present there is more than a primary lesion, for there is a harsh, brassy, or rattling cough, or enlarged lymphatic glands are found, or there are infectious and breaking down of the lymphatic glands, or tuberculosis due to reinfection from the primary focus. The fact that there is no primary lesion cannot be proved.

\* Read before the New England Pediatric Society, Apr. 25, 1916.

trition, anemia, failure to gain, or loss in weight in spite of good feeding, indigestion; and it seems to me that these early cases have a marked intolerance for fat, so that if in a case of chronic indigestion from fat the history does not give a previous carbohydrate injury, I am suspicious of tuberculosis.

If a primary lesion can be kept as such the infant is safe, hence the treatment is to recognize the primary lesion, prevent secondary changes in it and extension from it, and to prevent reinfection from without.

The recognition of the primary lesion takes us into the realm of physical examination, but it is important enough to speak of it here under treatment. The primary lesion from its nature is represented by a localized mass of lymph glands, because the primary focus or entrance point cannot be demonstrated during life. This mass of glands is easily seen and felt in exposed places, as the neck, axilla, or groins; palpable in the abdomen as mesenteric glands; made out in the chest by auscultation and percussion, and confirmed by x-ray. The Pirquet test is reliable, if obtained, and is corroborative evidence; but one test may not be sufficient, and it may be necessary to raise the susceptibility by a subcutaneous injection of tuberculin. A mass of mesenteric or bronchial glands and a positive Pirquet without enlarged glands elsewhere, means definitely a primary lesion. Bronchial glands without a recent acute respiratory infection in an infant, not doing well, even in spite of a negative Pirquet, I should consider tuberculous till proven otherwise by the disappearance of the glands, or by repeated Pirquets and general improvement. Two cases will serve to illustrate these points:

A boy 26 months of age was brought to me because he was thin, pale, underweight and not gaining; poor appetite, distended abdomen, undigested stools, too tired to play.

Examination showed a long, thin, pale infant. Lungs clear. D'Espine at the fourth dorsal, spinal dullness corresponding, interseapular dullness. Pirquet positive. Abdomen moderately distended. Nothing abnormal made out. Stools marked excess of soap. No x-ray taken. This was a case of primary tuberculosis of the bronchial glands with the entry in the lungs.

The treatment was rest, diet low in fats with broths, green vegetables and cereals, fresh air day and night, out doors when weather permitted. The rest prescribed was twelve hours at night, as much in the day as he was willing to take and not to be encouraged to play. He gained a pound and a half the first month and showed marked general improvement. Though the mother had been told that it would take a long time to bring about permanent improvement, the boy was so much better at the end of two months that she broke rules. He stopped gaining, lost his appetite, and was peevish. With no other change but enforced rest he again improved rapidly, and when last seen after a year and a half was doing well.

A girl, 18 months, brought to me for indigestion, anemia, large abdomen.

Examination showed a thin, pale infant, nervous and precocious. Chest negative, no signs of bronchial glands. Abdomen much distended so that nothing definite was felt, tympanitic throughout. Stools large and soapy. With regulation of diet, rest, and enemas, the distention was relieved so that I could palpate a mass of large mesenteric glands. The milk supply was so questionable that with the findings I made the diagnosis of primary tuberculosis of the mesenteric glands with the entry in the intestine.

The treatment consisted mainly in rest. With moderate quiet there was no gain in the symptoms. At 20 months she was put to bed and kept flat, restraint used when necessary. At 22 months the weather permitted her to stay out night and day, and she stayed out for a year. She was unhappy even in midwinter if taken in the house for more than feeding and bathing. The gain was slow. After ten months' quiet she was allowed freedom on a large bed in the house for one hour daily but not allowed to walk. Several attempts had been made to give more freedom, each time with return of peevishness and indigestion. At the end of a year she was digesting well, gaining color, glands palpable but half the size. The temperature never went above 101° and whenever even a slight fever there was accompanying indigestion and bad stools. Now at four years is doing well and has just recovered from pertussis.

The object of treatment in these cases is to get the infants in such good physical condition that they can fight against any disturbing element absorbed from the primary glands, and to give the primary glands a chance to be walled off and become inactive, for they are never healed. There are three factors essential in the treatment—rest, fresh air and sunlight, suitable food. Rest, I think, is far ahead the most important, and I mean by rest inactivity sufficient to get gain in digestion and weight. Though this stage is called chronic glandular tuberculosis, it is a fairly active process, and active tuberculosis demands rest. If later lung or bone tuberculosis needs rest, it is just as reasonable and necessary to give it at this stage. It may seem at first thought that enforced rest might be difficult to maintain and might not be good for the infant, but if one has ever treated tuberculosis of the spine he will know of children on bed frames for months and remain in good general condition. The little girl mentioned was very happy, and it was necessary to pin her down only when she began to feel well. She did not ask to walk, and talked of the time when she would be well enough to be up and walk like other children. It is not necessary to fasten these cases to bed frames. A stout sheet, with holes for the head and arms, can be pinned to the bed, and affords sufficient restraint. The rest should be persisted in till long after the symptoms have been relieved, and then resumed gradually, according to conditions.

The infant with a primary lesion should be protected from diseases affecting the region

drained by the primary glands, because the new infection will wake up the tuberculosis, the glands will break down, and there will be discharge of bacilli into the lymph or blood stream, with the resulting secondary forms. Tuberculosis following measles or pertussis is the result of waking up a pre-existent primary bronchial gland tuberculosis by the new infection draining into the glands. Acute miliary tuberculosis may follow acute intestinal diseases by inflaming mesenteric glands which are already tuberculous. However, an infant with primary mesenteric tuberculosis may have pertussis without any unusual concern. Hence it is important to caution parents to be more than ordinarily careful not to expose infants with a primary lesion to contagious diseases or to any other infection.

The treatment of tuberculosis in infancy comes essentially to treatment of the primary lesion and the maintenance of it as such. The important factors in the treatment are suitable food, fresh air, and rest sufficient and persisted in long enough to insure good nutrition and gain in weight. As long as the tuberculosis is kept primary, the infant is safe, and unless tuberculosis is recognized earlier than the secondary forms, little or nothing can be done in treatment.

### Address.

#### THE PORTRAITS OF FLORENCE NIGHTINGALE.

By MAUDE E. SEYMOUR ABBOTT, B.A., M.D.

*McGill University, Montreal.*

(Continued from page 367.)

#### III. THE PERIOD OF THE CRIMEAN WAR. (OCTOBER, 1854, TO AUGUST, 1856.)

PLATE VII.)

This portrait,\* one of the best known of the earlier pictures of Miss Nightingale, shows her, in garb and visage of the pre-Crimean days, seated on what is evidently a portico at Scutari, overlooking the Straits towards Constantinople. "I have not been out of the Hospital yet," she wrote, ten days after her arrival, "but

the most beautiful view in all the world lies, I believe, outside my door."

As will be remembered, the Crimean War was waged between Russia and Turkey, with Great Britain and France ranged as allies on the latter side. The battlefield was the Crimean peninsula on the northeastern border of the Black Sea, and the bloodshed was so great as to almost parallel the horrors of today. The British public accepted with resignation the news of the sacrifices in the field. But it met in a different spirit the alarming reports that followed immediately upon the news of the Battle of Alma, fought on September 20, 1854, of the ravages which neglect and disease were making among the multitude of the wounded, under the complete lack of sanitation that prevailed among the British troops. Not only were the hospital supplies, that had been freely sent out, unavailable for use through misunderstandings with the Turkish customs and other stupidities, so that the men were unclothed and unfed, and all sanitary measures neglected, but there was an entire lack of proper attendance for the sick, the skilled female nurses employed by their French allies providing an invidious comparison. A letter to the *Times* from its correspondent, William Howard Russell, exposing these defects in no measured terms, and calling upon England for redress, evoked a storm of indignation that swept the country. Miss Nightingale's training and personality were well known to a large circle of influential friends, and, moreover, her excellent administration of the "Governments Home" had brought her into touch with another side of the philanthropic public. The letter to the *Times* appeared on October 12. On October 14, under the action of a small committee, headed by Lady Maria Forester, she wrote to her friend Lord Sydney Herbert, who was then Minister at War, asking for authority to go out at her own expense at the head of a small band of five nurses. It is one of the coincidences of history that her letter to Lord Herbert crossed one from him to her, asking her, in the name of the British War Office, to undertake this task, and urging for acceptance of it on the ground that she was the only person in England who could make it a success, and promising for individual authority over the "Female military nursing establishments in the East" and for medical supplies. On October 21, five days after the matter was formally settled, she sailed for the East, and the

\* See JOURNAL, page 414.

PLATE VII. FLORENCE NIGHTINGALE AT SCUTARI.

From an Allen print of a drawing by Wandesforde, engraved by W. Wellstood.

head of thirty-eight nurses, of whom twenty-four belonged to the Roman Catholic and Anglican sisterhoods and the remainder were untrained. During these five days of selection of candidates and all the mass of detail involved in the organization of such an expedition, as also in all the exigencies of the uncomfortable voyage out, the most noteworthy thing about Miss Nightingale was her absolute calm, and her quiet control of the situation.

The groups of military hospitals in the East bore to each other something of the relationship that the field and base hospitals of our forces do now. On the Crimean peninsula, in the immediate neighborhood of the conflict and amongst the adjacent hills, there were, in addition to the regimental dressing-stations, four large general hospitals, some established in huts, others in buildings. On the opposite, that is, the southwestern, side of the Black Sea, across the Bosphorus from Constantinople and overlooking the Sea of Marmora, were the three great British military hospitals of Scutari, two of which, the General and Barrack Hospitals, were under the jurisdiction of Miss Nightingale, as also were all the hospitals in the Crimea, and for a time those at Koulali, four miles distant from Scutari. It was to the great Barrack Hospital of Scutari that she came on arrival, and there she had her headquarters. The abuses complained of in the *Times* were especially evident here because of the great overcrowding, the more unhealthy situation, the prevalence of cholera and other infections, and the fact that the means of transport across the Black Sea was very poor, so that the wounded arrived at Scutari in the last stages of exhaustion, in a condition when the lack of suitable food and the general inefficiency worked greater havoc.

The party arrived at Scutari on November 4, 1854. The Battle of Balaklava had been fought on October 25, and that of Inkerman on the day before their arrival, and the wounded were pouring in. The hospital was a huge place, capable of accommodating over 2000 patients (the maximum at one time was 2434, on December 23, 1855), and containing, in its overcrowded state, over four miles of beds, eighteen inches apart. In a letter written on November 14, Miss Nightingale writes that there were 1715 sick and wounded (among whom were 120 cholera patients), in this hospital, and 650 in the other building, called the General Hospital, of which they also had charge, "when a message came to prepare for 510 wounded arriving in half an hour from the dreadful affair at Balaklava. Between one and nine o'clock we had the mattresses stuffed, sewn up, laid upon the floor, the men washed and put to bed, and their wounds dressed." It was with such numbers and with similar emergencies, under circum-

stances of extreme complexity, that Miss Nightingale had to cope, during that first six months.

The fact that there was gross maladministration in every department of these hospitals at the time of her arrival, has been clearly established by the Royal Commission appointed at the time. The trouble was partly due to an organization without central authority, partly to gross ignorance of ordinary hygiene, partly to the want of the woman's touch, and in part doubtless to the real lack of capacity of certain officials to deal with a novel situation. Miss Nightingale brought all her powers of tact, courage, judgment and resolution to meet the exigencies of the case. The large public funds that had been placed at her disposal by the *Times* and other sources, as well as her own private income, enabled her to tide over a situation otherwise hopeless; but the problem remained to meet these urgent necessities within the limitations set by military rigidity and professional jealousy, for she realized from the outset that strict discipline must be observed by herself, and a proper subordination to the medical officers in charge. Much has been said of her "irregular" methods of cutting the Gordian knots of her dilemmas by supplies from her own reserves or by deliberate and unauthorized invasion of the purveyor's stores. But she never neglected to support such action by a medical requisition, and investigation shows that she never set authority causelessly aside. Rather she had the insight of that perfect discipline, which recognizes the point at which the breaking of the *letter* is the fulfilment of the *spirit* of the law!

Many of the difficulties are detailed in her letters to Lord Herbert, with suggestions for their redress. Thus, on her arrival there was no provision for the cleaning of the hospital, "not a basin, or towel, or piece of soap, or a broom," and her first requisition was for 300 scrubbing brushes! The patients' linen was not washed, and the bedding was only rinsed through in cold water, for the contract made by the purveyor with this object broke down before the convoys from Inkerman came in. Her first step was the renting and equipping of a Turkish house as a laundry, and the placing of the soldiers' wives at the washtubs. There was no clothing in the purveyor's stores, while, by a curious command, the soldiers had been required to leave their knapsacks before the Alma, in order to "march light" towards Sebastopol. In consequence the wounded arrived half naked and destitute of kit where they to leave the hospital. "I am clothing the British Army," she wrote. Again on her arrival she found the entire cooking done in thirteen large boilers, with no provision whatever for extra diets or special delicacies between courses, and by an extremity of red tape so that rations

were served *raw* in small quantities for each patient. "This practice," writes Miss Nightingale to Lord Herbert, "seems invented on purpose to waste the time of as many orderlies as possible, and it makes the patients' meals late, because it is impossible to get the diets thus drawn, cooked before three or four o'clock. The scene of confusion, delay, and disappointment, where all these raw diets are being weighed out by twos, and threes, and fours, is impossible to conceive, unless one has seen it, as I have, day by day. Why should not the Commissariat send at once the amount of meat, etc., required, to the kitchens, without passing through this intermediate stage of drawing by orderlies?" One of the most important measures introduced by her at the Barrack Hospital, was the opening, within 10 days of her arrival, of two extra diet-kitchens, and the placing of three supplementary boilers for arrowroot on various staircases. A few months later the great Soyer joined her as a volunteer, and took over the management of this invaluable part of the work.

And so with a thousand other details of management and equipment. She organized relief measures for the women camp followers, provided reading rooms for convalescent soldiers, engaged and superintended 200 builders in the emergency repair of a large part of the hospital, trained orderlies in sanitary measures, and herself did the work many times of a sanitary engineer, everywhere applying the expert's touch. But all this would have been ineffectual had she not had behind her own action the intelligent and informed power of those in authority at home. Her long days were followed by nights of letter-writing, when she indicated clearly to high sources what the necessary reforms were, and just how they should be carried out. Not only had she the loyal support of Lord Herbert and his colleagues, but the Queen herself was behind the prompt execution of her suggestions, and this was one of the most important sources of what was called by her enemies "The Nightingale Power." Among other measures enacted at her suggestion, it was due to the Executive Sanitary Commission, appointed in the winter of 1855, to act with plenary powers on the spot, that the horrible sanitary conditions of the hospital, which may be said to have overlain a great cess-pool, were removed. The death rate fell as the result of the action of this Commission, with remarkable rapidity.

But there was still another side of her activity—and that the ceaseless keynote of the whole, to which all her functions of administrator and reformer were, in a sense, secondary. "A Ministering Angel Thou!" Her devoted care of the patient, personal sympathy for the sufferer, skillful tending of the exhausted, and faithfulness to the dying—all those qualities that went to make the Lady-in-Chief at once the Queen of Nurses and the adored of the

wounded soldiery, shone day and night through those crowded wards at Scutari like the beam of her own lamp!

In the spring of 1855 Miss Nightingale crossed the Black Sea to the Hospitals of the Crimea and remained there for some time. The physical strain upon her here was great, for the several hospital buildings were distant from each other, and she was obliged to go from one to another, often in the depth of night, over rough country. With her strength undermined by the strain of the work at Scutari, she fell ill of Crimean fever, and nearly died. It was when the news of her recovery reached an anxious England, that the popular feeling for her, which had been growing stronger ever since the day it was discovered that the "Mrs. Nightingale" of the Nursing Expedition was a young and beautiful woman, and which was being constantly enhanced through countless grateful letters home from wounded and dying soldiers, burst all bounds, and a wave of tenderest enthusiasm swept England from shore to shore. A public meeting was called in London "to give expression to the general feeling that the services of Miss Nightingale in the East demand the grateful recognition of the British people." The room was crowded to suffocation with the flower of England's men and women, her own parents among them. The speeches were beautiful, and were touching to a degree in their perfect recognition of the single-minded spirit in which her wonderful work was done. Dearest of all to her heart—perhaps the only part of it all for which she really cared at all—was the joy that this public recognition of her work brought to her parents and to her sister, Lady Verney, long since reconciled to her purpose, and now understanding her at last.

It was at this meeting that the Nightingale Fund was inaugurated, "to enable her to establish and control an Institution for the training, sustenance, and protection of nurses, paid and unpaid." This fund was later applied by her to establish a training school for nurses at St. Thomas's Hospital. The flood of popular enthusiasm rolled on through the British Dominions, and public meetings in support of her fund were everywhere held. And the Queen honored her with a beautiful jewel, especially designed for her by the Prince Consort.

After recovery from her illness, Miss Nightingale was urged to return to England, but she insisted on remaining at her post, part of the time at Scutari and part at the Crimea, until after the termination of the war. It was on August 4, 1856, four months after the Treaty of Peace was signed, that she reached again her native land.

Public excitement was intense at the thought of her expected return, but, as Lord Ellesmere had said, speaking on May 5 in the House of Commons, "she is probably planning now how

to escape as best she may, on her return, the demonstration of a nation's appreciation of the deeds and motives of Florence Nightingale." She arrived at Lea Hurst from Paris unrecognized, under the name of Miss Smith, and walked unaccompanied from the little station to the protection of her home.

Disappointed of a public demonstration, the Press overflowed with admiring tributes in poetry and prose. With his usual timeliness, Mr. Punch published several excellent poems. One of these, which appeared on August 23, 1856, mirrors so well the sympathetic understanding and the real affection that swayed the British public of her day, that it is in the truest sense historic, and for that reason may be quoted here.

#### THE NIGHTINGALE'S RETURN.

"Most blessed things come silently, and silently depart.

Noiseless steals springtime to the year, and comfort to the heart.

And still and light, and gentle, like a dew, the rain must be

To quicken seed in furrow and blossom upon tree.

"Nile has his foaming rapids, freshets from mountain snows,

Yet, where his stream breeds fruitfulness, serene and calm he flows,

And, where he overbrims, to cheer his banks on either side,

You scarce can mark, so gradual, the swelling of his tide.

"The wings of angels make no stir as they ply their work of love,

Yet by the balm they shed around, we know them that they move.

God spake not in the thunder, nor the mighty rushing blast,

His utterance was in the still small voice that came at last.

"So she, our sweet Saint Florence, modest, and still, and calm,

With no parade of martyr's cross, no pomp of martyr's crown,

To the place of plague and famine, foulness and wounds and pain.

Went out upon her gracious toil, and now returns again.

"No shouting crowds about her path, no multitude's hot breath,

To fan, with winds of vanity, the doubtful fires of faith.

Her path by hands official all unsmoothed, her aims decreed,

By the Levites, who, when need was, passed on the other side.

"When titles, pensions, orders by random hand are showered,

'Tis meet that, save with blessing, she still should walk undowered.

What title like her own sweet name with the music all its own?

What order like the halo by her good deeds round her thrown?

"Like her own bird, all voiceless when the daylight songsters thrill,

Sweet singer in the darkness, when all songs else are still,

She, in that night of darkness that turned other hearts to stone,

Came, with soft step and gentle voice, yet wise and firm of tone,

"Think of the prayers for her, that to praying hearts came back

In rain of blessings, seeming still to spring upon her track.

The comforts of her graciousness to those whose road to death

Was dark and doubtful till she showed the light of love and faith.

"Then leave her to the quiet she has chosen. She demands

No greeting from our brazen throat, and vulgar clapping hands.

Leave her to the still comfort the saints know that have striven.

What are our earthly honours? Her honours are in Heaven."

Punch, Aug. 23, 1856.

#### IV. THE PERIOD IMMEDIATELY FOLLOWING THE CRIMEAN WAR. (1856-1861. PLATES

##### VIII, IX, X, XI.

The dissimilarity between the early and the late portraits of Miss Nightingale has often been remarked. This is not entirely due to the fact that the earlier ones are mostly light crayon drawings, the later, photographs "taken by commandment of the Queen" on her return from the East; nor is it to be explained by the natural changes occurring in the transition from young maidenhood to early middle age. There is in the best of these later portraits to be clearly traced the birth of a great experience. She has seen and partaken of the travail of the world's tragedy, and it has left its indelible mark upon her face. The qualities, too, that she has gained in the great conflict are visible. This is especially true of the charming little head shown in Plate IX. Endurance, unflinching decision, tempered with the kindly tolerance born of a great sympathy, even a humorous appreciation of the frailties of officialdom, are all expressed in the fine curves of the mouth, while in the eyes is the deep contentment of one who has seen the Vision, and knows of the foundations of her faith.

During the five years following the Crimean War, and especially during the immediately succeeding time, Florence Nightingale needed every spark of spiritual force which had come to her from the fires through which she had passed. She and her friend Sydney Herbert, with other loyal coadjutors, were together to shoulder a burden of reform under which immediate action was so imperative, that only by unrelaxing effort could results be achieved. The strain was of a different kind from that in the Crimean hospitals, but the task to be accomplished was even more gigantic. On the other

hand, the unremitting energy demanded of her told upon her weakened frame, and she became permanently invalided, and saw all her dreams of an active life among the hospital training schools she was about to inaugurate, permanently denied her. Moreover, during these years she was to see Lord Herbert himself sink under the work. He died in 1861, before he had accomplished what she called the "main-spring" of the whole,—the reform of the internal organization of the British War Office. His death was a blow from which she never quite recovered. During these five years they were in constant communication and consultation, and were allies in the truest sense, giving to each other a comradeship and a loyal support and understanding that was essential to the great results that they attained. Their work was in a sense complementary, for she had the administrative, he the political and executive mind (Sir Edward Cook). Their relationship is to be recognized as one of the great friendships of all time, and in a sense it is unique in history. Sydney Herbert was a man of immense charm, with a devoted wife who shared his every thought, and between whom and Miss Nightingale there existed a

close intimacy and a strong spiritual tie. Not the least part of the great inheritance that Florence Nightingale has left to her sex, is the fact that such true friendship between man and woman can and does exist.

Only the first few days of Miss Nightingale's return to England were given up to personal matters. The consciousness pressed home that her experience in the Crimea must not be allowed to sink, even temporarily, into oblivion, but that the iron of public opinion must be struck while still hot, if the evils under which the soldiers had suffered were not to be repeated and perpetuated. The remarkable change wrought in the mortality of the hospital at Scutari by Miss Nightingale and her supporters during the first six months of the war was to be looked upon as a sanitary experiment of the most brilliantly successful kind. It was of vital importance to the future welfare of the army that the evils fought against and corrected in the Crimea, should be exposed in a Royal Commission of enquiry, and that action should be taken against their repetition while indignation still burned hot in public sentiment. Miss Nightingale was keenly alive to the horror that had surrounded her in the Crimea, and never forgot that mortality rate of 60% in the Scutari Hospital during the first weeks of her stay there, that blackened the good fame of the British Army regulations. Among her private notes of 1856 is written, "I stand at the altar of the murdered men, and while I live I fight their cause."

PLATE IX. MISS NIGHTINGALE ON HER RETURN FROM THE CRIMEA.

From a photograph in the collection of the late Mr. J. B. Leamont, Montreal, reproduced also by the London Stereoscopic Company.

The required reforms were already the subject of serious discussion between herself and Lord Herbert. It was at this juncture on August 23, 1856, a fortnight after her return, that she was given the opportunity by an invitation to Balmoral Castle, of personally setting forth to Her Majesty the sufferings of the Queen's Army in the East, and their possible means of redress. Her preparation for the interview was thorough. In consultation with those who had the cause of medical reforms at heart, by the study of statistics, by enquiries; and by the collection of her own notes and memoranda, she armed herself to make the utmost use of her great opportunity. Nor was she disappointed. The Queen and the Prince Consort together gave her their fullest attention. "She put before us," wrote the Prince in his diary, "all the defects of our present hospital system, and the reforms that are necessary. We are much pleased with her; she is extremely modest." Nothing could be done, however, without the action of Ministers, and although she returned to London apparently successful, many months of delay and strenuous insistence were to elapse before a Royal Commission, with Lord Herbert as chairman, could be appointed. This took place by Royal Warrant on April 26, 1857, shortly after the publication and circulation of Miss Nightingale's comprehensive private report, entitled, "Notes Affecting the Health, Efficiency, and Hospital Administration of the British Army." This book created a profound impression. Sir John McNeill writes repeatedly in appreciation of its clearness and vigor, and ends, "I think it contains a body of information and instruction such as no one else, so far as I know, has ever brought to bear upon a similar subject. I regard it as a gift to the Army, and to the country altogether priceless."

The Commission appointed, its duty was to submit a report of the abuses and projected reforms, to the House of Commons. Miss Nightingale's own evidence took the form of thirty-three pages of written answers to questions in the "Blue Book" report. "It was distinguished," in the words of an Army doctor of the time, "by a clearness, a logical coherence, a pungency and abruptness, a ring as of true metal, that is altogether admirable."

The Report itself was written by Mr. Herbert, with much assistance from Miss Nightingale. It recommended the appointment of four sub-commissions, whose functions should be: to put the barracks in sanitary order; to organize a statistical department; to institute a medical school; to reconstruct the Army Medical Department, and to revise its hospital regulations. To it was appended a statistical study made by Miss Nightingale, of the civil and military mortality statistics in certain London parishes, from which the startling fact revealed itself that the rate of mortality among the sol-

of Dr. Collins Warren, Boston.

diers living in barracks was five times as great as that of civilians living at home. To force this existing fact, namely, that the Army in time of peace was being exposed to the effects of bad sanitation with disastrous results, upon the attention of the House, meant a hearing, which perhaps the evils of the Crimean War, already becoming a thing of the past, might possibly not obtain, even so soon after the terrible events. After much activity on the part of all interested, the Report was formally acted upon, and the four sub-commissions authorized. They immediately set to work, with Miss Nightingale the heart of each, herself now ill and weak from the prolonged exertion of these strenuous months, after the strain in the Crimea. It was quite possibly the effects of these months of unrelenting exertion, at a time when her body demanded rest, that left her a permanent invalid. A diagnosis of Miss Nightingale's malady has not, so far as we know, been framed, but her own statement about herself in her letters to her medical friends, suggest that she suffered from some form of cardiac insufficiency associated with cardiac dilatation and a paroxysmal tachycardia. Even at her lowest ebb, she never put aside her harness, but met emergencies as they arose, until in February, 1858, the various investigations made and the resulting recommendations embodied in a second Report from the Commission.

The results were worthy of the high prize she paid in the permanent sacrifice of her health. Each commission carried out its work through to a successful issue, and the results that are felt more and more in the right directions. The Crimean War, which had taken a leading place in her life, and which Miss Nightingale's "Notes" had made the greatest importance of the world's history, peace, and political life, was now being

in it, and which made it possible for her to inspire these far-reaching reforms.

PLATE XI. MISS NIGHTINGALE  
(IN 1858)

From a photograph by Goodman in  
the possession of Dr. Collins Warren,  
Boston.

The results of the work of the four sub-commissions may be briefly summarized as: the better barrack accommodation and military hospital construction, which have resulted in the improved health of the British soldier at home today; the revision of army medical statistics and the establishment of British army statistics on a higher plane than that of any other country in the world at that time, a task in which the statistical skill, energy, and persistence of Miss Nightingale was united with the experience of the celebrated Dr. William Farr; the foundation of the Army Medical School, and the splendidly equipped Royal Medical College; and the formulation of a code for regulating the relative duties of regimental medical officers, and organizing the detail of the internal administration of military and other hospitals.

The third sub-commission, to establish an Army Medical School, had the longest and weariest struggle against the obstruction of subordinates of them all, but it accomplished most important results. The Army Medical School, afterwards removed to Netley, was peculiarly Miss Nightingale's child, and she watched over its early progress with earnest solicitude. In every part of the administration the professors sought her assistance, and she made a successful fight, against much opposition, to have pathology recognized in the professoriate. Her services as the true founder of the School were acknowledged at the time. Dr. Longmore, the professor of military surgery, told the students that it was she "whose opinion, derived from large experience and remarkable sagacity in observation, exerted an especial influence in originating and establishing this school." "For

originating this school," wrote Sir James Clark, "we have to thank Miss Nightingale, who, had her long and persevering efforts effected no other improvement in the army, would have conferred by this alone an inestimable boon upon the British soldier."

Apart from the work of the commissions, many other army reforms were instituted by Mr. Herbert and inspired by Miss Nightingale. Such were the committee to reorganize the Army Hospital Corps and the Soldiers' Recreation Clubs. The latter were organized by them with much success, not only in England, but at Gibraltar, Chatham and Montreal, which was then a military post. The regimental institute attached to every modern barrack is the direct outcome of this branch of their pioneer work.

Such is a brief outline of the epoch-making work carried on by Sydney Herbert and Florence Nightingale during these five years immediately following her return from the East. Great as it was, however, these reforms in army sanitation were not by any means the only side of her activities during this period. Of equal importance was: (1) her work in the reform of modern hospital construction as a whole, (2) in the introduction of statistical forms for hospital use, and (3) especially in the foundation of modern nursing.

Miss Nightingale's prestige in matters of hospital construction was recognized before her book, "Notes on Hospitals," appeared, in 1858. This book was written in connection with her work on the first sub-commission, and is a technical study of the subject supplemented with numerous maps and diagrams, and recommending the elementary principles of sanitation, which were not then generally recognized, and the pavilion system. "It appears to me," wrote Sir James Paget, "to be the most valuable contribution in application to medical institutions I have ever read." After its appearance she was widely consulted on hospital construction at home and abroad, and revised the plans of many hospitals erected in Great Britain, Germany, Belgium, Spain, France, India and America.

Her work as a *statistician* has already been referred to and her alliance with Dr. William Farr. Her statistical forms for the use of hospitals were presented at the International Congress in London in 1860, and were introduced in the leading London hospitals. On June 21, 1861, a meeting was held at Guy's Hospital and it was unanimously agreed—by delegates from Guy's, St. Bartholomew's, St. Thomas's, the London, St. George's, King's College, the Middlesex, and St. Mary's—"that the metropolitan hospitals should adopt one uniform system of registration of patients; that each hospital should publish its statistics annually, and that Miss Nightingale's Model Forms should, as far as possible, be adopted."

Her work in the *foundation of modern nursing*

ing has been described as one of the three great contributions of the nineteenth century to the relief of human suffering in disease. In the alleviation which it has supplied it takes rank with the discovery of anesthesia by Sir James Simpson, and asepsis by Sir Joseph Lister.

The Nightingale Training School for Nurses was opened at St. Thomas's Hospital on June 24, 1860, under the administration of the Nightingale Fund, which amounted to £44,000, raised throughout the British Empire, as a tribute to the Crimean heroine in 1855. Miss Nightingale planned every detail in its organization, and assisted the first matron, Mrs. Wardroper, in the discharge of her activities. She herself interviewed and accepted candidates and others, and afterwards preserved the closest touch with the pupil nurses and graduates. The influence of the school spread rapidly, and the Nightingale nurses, both in Great Britain, the Colonies, and the United States, made their way as superintendents. The Blockley Hospital in Philadelphia, and the Montreal General Hospital here, were two of those that owned a Nightingale superintendent. In Germany, Sweden, France, and Austria, too, the lead was followed, and nurses were trained along the same lines. Thus the seed that was carried by Pastor Fliedner from Elizabeth Fry in London to Kaiserswerth in Germany, was transplanted by Florence Nightingale again on English soil, and grew into a mighty tree.

It has been well said that Miss Nightingale did not originate the idea of trained nursing of the sick, for there were sisterhoods and great nurses before her time. What she did do was to place the art of nursing on the plane of a profession, and to transfer it, as the books of the British census show, from the category "Domestic," in which it stood before her time, to that of "Medicine." Both by precept and example she taught and tried to instill into her nurses the principles and the code of honor that raise an occupation into a profession. She raised a great enthusiasm among the women of her time, many of whom grasped her meaning, and worked with her to attain this end. She took it out, too, of the place in which it had been put before her time by the religious orders, who regarded their nursing chiefly as a means of self-abnegation and humiliation. She believed, no one more strongly, that the true nurse must have a sense of vocation, and that without it she should not enter the profession, and with her "nursing was a sacred calling, only to be followed to good purpose, by those who pursued it as the service of God, through the highest kind of service to man." But she recognized also, that the skilled services of the trained nurse should form an honorable means of livelihood, and insisted on the public recognition of this fact. Miss Nightingale never thought or cared about what has been called women's rights, but she was essentially a pio-

neer in the interests of her sex. By the high estimate and value she placed upon the skilled services of women in a capacity in which only they can serve, she raised the public sense of the value of those services all along the line, and there is probably no other woman to whom modern women owe so much. Her words on the subject of the modern feminist movement, which was just beginning in her day, and which close her little volume "Notes on Nursing," are an epitome of wisdom, and strike directly home.

*"I would earnestly ask my sisters to keep clear of both the jargons now current everywhere (for they are equally jargons); of the jargon, namely, about the 'rights' of women, which urges women to do all that men do, merely because men do it, and without regard to whether this is the best that women can do; and of the jargon which urges women to do nothing that men do, merely because they are women. Surely woman should bring the best she has, whatever that is, to the work of God's world, without attending to either of these cries. It does not make a good thing, that it is remarkable that a woman should have been able to do it. Neither does it make a thing bad, which would have been good had a man done it, that it has been done by a woman.*

*"Oh, leave these jargons and go your way straight to God's work, in simplicity and singleness of heart."*

The "Notes on Nursing" was published in 1860. It is the best known of her writings, and in the purity of its English, the vigor and simplicity of its style, and the fundamental soundness of its teaching, is in the highest sense a classic. It is a book which anyone may read with delight and information today, and should be republished in popular form. Florence Nightingale possessed the literary faculty in a very high degree, and was a voluminous writer, but she held this, as she did her social accomplishments, very lightly, to be used only as a means to an end, and to be considered, rather as a "temptation" to be avoided, that might lead her away from the purpose to which she had consecrated herself, and never as an end in itself. This is the reason, that although her contributions to the literature of her time are as important and probably as numerous as those of her illustrious contemporaries, Mrs. Gaskell, George Eliot, and Harriet Martineau, they are not recognized as such, for they are largely on technical subjects and many of them are hidden in the Blue Books of the day. It is only when she is dealing, almost as it were by accident, with subjects of wider and social scope, that her power of literary expression and her clearness of vision in the realm of abstract thought are fully revealed to us. The best illustrations are to be found in her lengthy correspondence with such men as William Llewellyn and John Stuart Mill, and in her great religious and sociological treatise, entitled "Suggestions for

Thought to Searchers for Truth among the Artizans of England and to Searchers after Religious Truth," published in three volumes, containing 729 pages in all, by Eyre and Spottiswoode, London, in 1860. Her yearly "Addresses to the Probationer Nurses in the 'Nightingale Fund' at St. Thomas' Hospital," printed for a limited private circulation during the years 1873 to 1888, stand out also as models of clear diction embodying principles of deep ethical and spiritual force. The nineteenth century has been called pre-eminently the century of great women. It is from the literary and philosophic, as well as the philanthropic side, that Florence Nightingale possesses an eminent place within the circle.

(To be continued.)

## Society Report.

### NEW ENGLAND PEDIATRIC SOCIETY.

THE FORTY-FOURTH MEETING OF THE NEW ENGLAND PEDIATRIC SOCIETY WAS HELD IN THE BOSTON MEDICAL LIBRARY, FRIDAY, APRIL 28, 1916, AT 8.15 P.M.

The President, DR. A. C. EASTMAN of Springfield, Mass., was in the chair.

The following papers were read:

#### I. SOME PHASES OF THE RECENT EPIDEMIC OF "ACIDOSIS."

By P. H. SYLVESTER, M.D., NEWTON.

#### II. IDIOSYNCRASY TO COW'S MILK. ITS RELATION TO ANAPHYLAXIS.\*

By FRITZ B. TALBOT, M.D., BOSTON.

#### III. THE TREATMENT OF TUBERCULOSIS IN INFANCY.†

By W. W. HOWELL, M.D., BOSTON.

#### DISCUSSION.

DR. TALBOT (Dr. Sylvester's paper): Dr. Sylvester's paper has been very interesting and his experience is very much like mine. I want to draw attention to one statement which he made, that in speaking of acidosis and using the term acidosis, of the relation of ammonia to the total nitrogen in the urine as being of importance in determining an acidosis. This is in the main true when there is

sufficient protein in the diet. The total nitrogen in the urine depends upon the protein in the food while the ammonia is more or less independent, so the relation becomes distorted and has no significance when there is a low protein in the diet. This should be borne in mind when anyone is drawing conclusions from the ammonia ratio. In the cases which I saw, one thing impressed me a good deal and that was the loss of water due to the extreme vomiting which did not allow water to get into the body, and the diarrhea, which withdrew water and salts from the body. I personally subdivide these conditions that we have been dealing with this winter, and previous years, into vomiting with acetouria as shown by small amounts of acetone in the urine and vomiting—which is very common—and true acidosis. The only way that we have to determine true acidosis is by tests that are too difficult for physicians to use in their private work with the exception of the test recently advised by Marriott of Baltimore, in which the carbon-dioxide tension of the alveolar air can be determined very simply, by collecting the air in a rubber bag and running the air into a solution of 1/100 normal alkali and phenolphthalein, and comparing the resulting color with a set of tubes which give us known quantities of carbon-dioxide in the air. By them we can tell whether the alveolar tension is 40, 30 or 20, or even lower. It very rarely goes below 20. True acidosis is shown clinically by a diminished carbon-dioxide tension in the alveolar air. This is because, as Dr. Sylvester suggested, the salts are not present in large enough amounts to carry the carbon dioxide in the blood to the lungs. Clinically it is manifested by what we know as air hunger, and I believe that when we see air hunger we see acidosis, and when we do not see air hunger we have vomiting with acetouria. In some of the instances, I believe that what we call vomiting with acetouria does change into true acidosis, and I believe that the factor that decides whether it is or is not true acidosis is whether the body responds to alkali or not. The symptom upon which that is dependent in large part is diarrhea.

DR. SYLVESTER: (1) I would like to ask Dr. Talbot if he feels that there is any sharply dividing line between the children with air hunger with true acidosis, and children who have "vomiting with acetouria"? Do you think that the children who have vomiting with acetouria have sighing respiration or evidences of difficulty with respiration, or definite air hunger?

(2) Given a child who had a readily controlled acetouria with vomiting and who was having a certain amount of sighing respiration, would you put that in the same class as a child with a true acidosis?

DR. TALBOT (Dr. Sylvester's paper): (1) I think that true acidosis is not a disease but a symptom. It is a late symptom which occasionally comes in the conditions that we have been talking about.

(2) If there is deep respiration you have air hunger and this is true acidosis; the air hunger may be like the other symptoms, it may be pronounced or it may be mild, and it is impossible to draw a sharply marked dividing line between whether there is air hunger or whether there is not. In the cases of air hunger which I have seen it has come on very quickly within one or two hours' time.

\* See JOURNAL, page 409.

† See JOURNAL, page 411.

DR. CALDER (Dr. Talbot's paper): I wish to refer briefly to a case that came under my care. The baby was breast-fed, nine months old, when cow's milk was first given. This was taken all right and there was no vomiting, but the child had a very profuse urticaria in about one-half hour after taking. The breast milk was resumed and whenever attempts were made to give cow's milk in any quantity whatsoever the urticaria resulted and on several occasions an asthma with the urticaria. The child was given goat's milk once. This had to be forced and the child showed much more distaste for it than for the cow's milk. It was vomited almost immediately and was followed by a very intense asthma and urticaria. This child was nursed on the breast until one year, having cereals in the mean time and butter, which caused no general reaction although there was some local irritation where it had touched the skin of the face. This local irritation disappeared after the child had been given the butter for a few months. The child was brought along on cereals, butter and lamb juice, and to some extent on lamb meat, and potato, fruit juices and vegetables. The milk tolerance was increased by feeding the child  $\frac{1}{2}$  drachm every other day, gradually increasing the amount, it being six months before the child was able to take 8 oz. of cow's milk a day. This child had also an anaphylaxis to egg.

DR. TALBOT (after Dr. Calder's remarks on Dr. Talbot's paper): I was very much interested in the case that Dr. Calder reported. Evidently this baby was sensitive both to the milk of the cow and the goat, unless someone substituted cow's milk for goat's milk.

DR. TALBOT (Dr. Howell's paper): All the cases that we have had at the Massachusetts General Hospital with a positive von Pirquet under two years of age, except one, died. That one, so far as I know, is living. All the others that had negative von Pirquets that died that showed that they had tuberculosis, as I remember it, died of milinary tuberculosis. It is quite natural in infants dying of such disease, I think that there should be no repair. If there is repair, they will get well. If they get well and die of something else, how can you tell whether the disease came on during the first or second year of life? My impression of this discussion is that we are talking about human tuberculosis. I feel that in discussing this question, we have neglected bovine tuberculosis. At present in the findings in tuberculosis of the glands our impression is in the post-mortems, that more than half of them gain their entrance through the mesenteric glands and for that reason, and backed up by the work of the Royal English Commission, it looks as if much of the tuberculosis of infancy was of bovine origin. Again if it is of bovine origin, I should think if one tubercle bacillus were fed to that child every day that that child would have 1000% less chance of life than if only one tubercle bacillus gained entrance and the body had a chance to kill it.

DR. DENNY (Dr. Howell's paper): Dr. Howell expressed the opinion that there was danger of re-infection in children and Dr. Dunn expressed the opinion, as the result of his pathological work, that there is very little danger of re-infection. It seems to me that this is a very important question to know more about. It has a very practical bearing on the question as to whether it is safe to send a young child to a hospital where there are cases of open tuberculosis. I would like to hear some other opinion on that subject.

DR. SMITH (Dr. Howell's paper): Dr. Howell says that these cases ought to be treated as tuberculosis, and that they always have the disease. I would like to ask what he calls these cases when they get to be 10 or 15 years old—does he say that they have tuberculosis then?

DR. SMITH (Dr. Howell's paper): I would like to ask what distinction is made between tubercular infection and tuberculous disease. That distinction is one that ought really to be made. As I understand the distinction, tuberculous infection means the presence of tubercle bacilli in the body which are not active; tuberculous disease includes all cases during the active stage. These two types of the disease should be differentiated, for the treatment is quite different.

DR. DENNY (Dr. Howell's paper): I have only two objections to bring forward to the conclusions in Dr. Howell's paper; one of them is really not an objection. He speaks of the lesion at the portal of entry and the associated lymph-node process, as if both were included under the term primary lesion. This, I think, might give rise to some confusion in connection with the question as to whether there is or is not a lesion at the portal of entry. It would be better, I think, to speak of the primary pulmonary lesion and the associated lymph-node process together, as the primary stage of tuberculosis, and to confine the term primary lesion to the process found in the parenchyma of the lung. The question as to whether there is such a primary lesion at the portal of entry has been one of the disputed points in the pathology of tuberculosis. In my experience, such a lesion can always be found if carefully looked for.

I have been working on tuberculosis a good deal at the Infants' Hospital, and one point which has struck us is the close relationship between tuberculosis and syphilis. I think that tuberculosis, like syphilis, can be divided into primary, secondary, and tertiary stages. Some authorities regard the phthisis of adults as representing the tertiary stage of an infection acquired in infancy. I am in doubt as to whether this is a true distinction, but many observers believe that the phthisis of adults does not represent a fresh infection from without, but represents the lighting up of an old process, or a retrograde infection.

Another point in which I differ from Dr. Howell is, when he speaks of the danger or frequency of fresh infection from without. The study of the pathological material which we have been engaged in has rather convinced me that this is not a very great danger and that it very rarely occurs, and that the various widespread manifestations so characteristic of tuberculosis in infancy and childhood do not represent a fresh infection from without, but rather an extension from the lesions of the primary stage. This extension appears to take place in a very well-defined way so that it can be treated as nearly all post-mortem cases.

The trouble with tuberculosis in infancy, as Dr. Howell has said, is that the danger is not recognized until the secondary stage is developed. The majority of cases of disseminated tuberculosis in infancy depends on the extension of a primary tubercular meningitis or a tubercular pneumonia to the lungs, bronchopneumonia, or some other form of pneumonia. The secondary stage, as Dr. Howell says, which has been very extensively studied, is the lighting up of tubercle bacilli which have been in the body since birth. I have seen a number of these cases in the American Journal of Pathology.

any good distinction between chronic pulmonary tuberculosis and the signs of the secondary lesions in the lungs found in children. It would be too much to say that chronic pulmonary tuberculosis is never found in the lungs of infants and children. Occasionally there is a condition of extremely increased activity of growth in the tiny primary focus which almost amounts to the lesions of phthisis. The usual changes in the lungs clinically may resemble consumption and may show the physical signs which are described in text-books as characteristic of phthisis and may run the same clinical course. But from the pathologic point of view these lesions are not the same as in the phthisis of adults, which represents an entirely different proposition. Tuberculous bronchopneumonia is the lesion characteristic of infancy and early life, acute phthisis being only rare.

We have been comparing the various clinical manifestations with anatomic findings. We have had a large number of tuberculous autopsies, but the main thing, as Dr. Howell says, is to make the diagnosis in an infant before the secondary stage has developed. That is the thing which has not been done. The diagnosis of tuberculosis either rests on finding signs of solidification of some kind in the lungs or on the existence of some other well-recognized form as meningitis or peritonitis. Without these signs, the diagnosis of the primary stage rests on three things,—the von Pirquet reaction, the enlargement of the bronchial lymph nodes, when they can be detected on physical examination, and when they cannot be detected, on an x-ray examination.

DR. DUNN (Dr. Howell's paper): The term infected with tuberculosis but not diseased is not applicable, because these infants are always in extreme danger. The number of infants which develop secondary processes which are fatal is very large. Another thing which bears on that point is that in children under two you practically never see the slightest tendency toward healing of the tuberculous lesion or repair. It is not such an important question as to how long we shall consider them subjects of tuberculosis, because there is absolutely no permanent way in which we can tell when the actual tuberculous infection dies out except through very careful examination of anatomic material. Certainly in children under two it seems to me to be a much better thing to regard every child that shows evidence of infection with tuberculosis as a victim of tuberculous disease and to treat it in that way.

DR. HOWELL: I made the statement that I criticized the terms tuberculous infection and infected with tuberculosis merely because I believe that the primary stage of tuberculosis or the primary lesion always gives symptoms—that is, when a baby is infected with tuberculosis he probably has a reaction at that time. He may have fever. I have never seen a case at the beginning of the primary stage but I believe there are always symptoms. So I do not see why he has not a disease merely because he does not have symptoms recognized as those of tuberculosis. He always has the glands, and they are active enough to keep up his reaction shown by the von Pirquet. He always reacts, so he always has a diseased process. The expression infected with tuberculosis always makes me think of the old physician who called a surgeon in consultation from Chattanooga, Tenn., to see a case of inoperable

uterine cancer. The surgeon asked the old physician if he had ever considered it was cancer, and he replied that he had never made up his mind that it was really cancer, but he had always suspected it was of a cancerous nature. To my mind the term infected with tuberculosis comes into that class. If you are getting symptoms that cannot be explained in any other way and find glands and suspect tuberculosis, treat it as a case of tuberculosis until there is improvement. At the Infants' Hospital we see a good many babies who die who might have been saved if the disease had been recognized early. Last Sunday we had 25 per cent. of the cases in the wards with tuberculosis, the disease having been recognized in only five cases before they were admitted, and they were in the hopeless stage at that time. I think it is a very dangerous thing to make a diagnosis between infected with tuberculosis and tuberculous disease. I believe if they once have it they always have it and they are always in danger.

### Book Reviews.

*Principles of General Physiology.* By W. M. BAYLISS, Professor of General Physiology. University College, London. New York: Longmans, Green & Co. 1916.

No general work on physiology which has appeared in recent years has been welcomed more eagerly or more deservedly than this book of Professor Bayliss. The facts it presents are of fundamental interest and importance to physiologists and to progressive medical men. Many of them have been hitherto available only in the original papers scattered over a large number of publications. In bringing these together in compact and readable form, an inestimable service has been performed.

The plan of the book is admirable. Each chapter ends with a condensed summary of its contents and references to the literature of special interest. A feature which adds greatly to the book is the series of portraits of leaders in physiological investigation,—a series in itself of great interest. The attempt has been made to present important facts that deal with the subject of general physiology. There is also a consistent effort to interpret these facts intelligently. Although, as the author admits, interpretation is often a matter of individual opinion, and therefore subject to error, his contention that a logical interpretation, even though finally shown to be erroneous, is better than a muddled presentation, will be approved by most fair-minded readers. A very complete bibliography covering 82 pages is inserted at the end of the book. No worker in physiology or medicine, who desires to keep abreast of current thought, can afford to disregard the facts presented in this book.

*Lateral Curvature of the Spine and Round Shoulder.* By ROBERT W. LOVETT, M.D., BOSTON. Third edition, revised and enlarged; with 180 illustrations. Philadelphia: P. Blakiston's Son & Co. 1916.

The third edition of any medical textbook means that it has been found useful and that the principles which it enunciates are considered by competent authority to be sound.

Perhaps no branch of orthopedic surgery has had such close attention concentrated upon it as the subject of scoliosis, its origin and its cure. Despite this fact we find today that its etiology is still unsettled and its treatment far from uniform. When men of such large experience as Schultes, in Zurich; Schanz, in Dresden; Lovett, in Boston,—all differ as to the most efficient method of its control, it proves that it is a subject that demands clear description of its symptom-complex, a lucid exposition of the different methods of treatment and a nice balancing of evidence as to the relative value of these methods. These demands the book meets in a fair and impartial manner and in addition devotes a chapter to the history of scoliosis and another to faulty attitude and round shoulders. It is a book which is extremely useful to both practitioners and medical students. It embodies results of wide personal experience and displays an intimate knowledge of the work of other men.

*A Manual of Practical Laboratory Diagnosis.*

By LEWIS WEBB HILL, M.D., Graduate Assistant, Children's Hospital, Boston. Boston: W. M. Leonard. 1916.

The author's frankly stated reason for adding this excellent manual to the many other existing works on laboratory diagnosis is to provide a volume of convenient and suitable size for carrying in the pocket, which shall afford for house officers and medical students a means of immediate ready reference, unconfused by the presentation of a number of alternate methods of performing any given test. Much material usually incorporated in laboratory manuals is purposely omitted, only that being included which is practical for use by the average medical man. Hence the Wassermann reaction, the Gold chloride test and various methods of tissue staining are not included, since they are not ordinarily performed by students, house officers and general practitioners, for whom this book is intended. The work is divided into eight chapters dealing respectively with the urine, the blood, the feces, gastric contents, spinal fluids, pleural and peritoneal fluids, sputum, and such miscellaneous topics as the Gram stain, the stain for spirochaeta pallida, the Schiek test, the von Pirquet test, tables of

Gram positive and Gram negative organisms and of diseases in which leucocytosis is present or absent. Each page is printed on only one side, the blank side thereby affording convenient space for notes. The book is illustrated with eleven figures and eight plates, four of which are colored, and is to be cordially commended to the use of those for whom it is intended.

*Back Injuries and their Significance under the Workmen's Compensation and other Acts.* By ARCHIBALD McKENDRICK, F.R.C.S.E., etc., Surgeon in Charge of Surgical X-ray Department, Royal Infirmary, Edinburgh. New York: William Wood & Company; Edinburgh: E. and S. Livingstone. 1914.

A small volume of 150 pages by McKendrick of Edinburgh. McKendrick is apparently both a surgeon and a roentgenologist. He seems to be also an excellent anatomist. He discusses in succession the structure of the spinal column, the muscles and fascia, the detail of examination and symptomology, and the various x-ray and other special methods of examination.

The book is an excellent little manual. In common with many other small volumes, it lacks a brief conclusion at the end of each chapter. This is perhaps of less importance in so small a volume, but would have been a distinct addition.

Dr. McKendrick does well to call attention so convincingly to this somewhat overlooked class of injury, which is too often a permanent disability to a working man or woman.

*Skin Cancer.* By HENRY H. HAZEN, A.B., M.D. Ninety-seven text illustrations and one colored frontispiece. St. Louis: C. V. Mosby Co. 1916.

Dr. Hazen of Washington, the author of this book, defines his purpose as an effort to gather under one cover the latest views on malignant tumors of the skin, and to give his personal experience, gained chiefly in the surgical, pathological and dermatological departments of the Johns Hopkins Hospital. The subject lends itself naturally to profuseness of illustration, and this feature has been very completely exploited by the author. Many of the illustrations, which have been contributed by the author's colleagues as well as by himself, are of great excellence, others could have been omitted without detracting from the general results. Much space is devoted to the subject of treatment, and the different methods and their applicability to individual cases are very fully and fairly set forth.

# THE BOSTON Medical and Surgical Journal

Established in 1832

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, SEPTEMBER 21, 1916.

## EDITORS.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## TRANSMISSION OF POLIOMYELITIS.

As the leading article in this issue of the JOURNAL, is published an important paper by Dr. Mark Richardson of Boston, formerly secretary of the Massachusetts State Board of Health, advancing a new theory of the transmission of poliomyelitis. The author reports investigations, experience, and arguments indicating that the rat-flea is really the responsible agent in the transmission of the disease, as in the case of bubonic plague. A similar suggestion has recently been made in New York, involving a mosquito as the possible transmitting agent. This contention, however, is as yet unproved. The confirmation of Dr. Richardson's theory must rest on further observation and experiment. If, as a result, the rat-flea is determined to be the actual transmitter of the infection of poliomyelitis, a cardinal step will have been taken toward the control of this serious scourge, and Dr. Richardson's theory established as a notable and beneficent contribution to medical knowledge and human relief.

## STATE CONTROL OF MEDICAL PRACTICE.

THERE is considerable dissatisfaction in various sections of the Commonwealth with that portion of the Workmen's Compensation Act which gives insurance companies the right to "furnish" medical attendance. This right to "furnish" practically is the right to "name" the physicians who shall treat injured employees. In his admirable article, which we print in another column, Dr. Francis D. Donoghue has pointed out "some medical aspects of the Workmen's Compensation Act" which should interest all physicians. He shows that the law, since it first became effective in 1912, gave insurers the right to "furnish" treatment and that only the liberal interpretation and the influence exerted by the Industrial Accident Board gave physicians a greater opportunity to render medical aid to injured employees than was contemplated when the law was passed, if we consider the wording of the original act.

The latest important liberal medical decision of the Board, that made in the Pecott case, was reversed by the Supreme Judicial Court, and physicians have become alarmed at the possible effect of this reversal. A campaign has been undertaken for the purpose of arousing medical men to the necessity for a change in the law. Many men argue for the free choice of physicians by injured employees alone; others think that either the Industrial Accident Board or the Insurance Commissioner should be given power to supervise exclusively this important matter; and the suggestion has been made, tentatively, that a list of acceptable physicians be prepared and that the selection of a medical man by either employee, employer, or insurer be restricted only to the names given in such a list.

It should be remembered, in considering new legislation, that unrestricted choice of physicians by employees will probably result in the establishment of a state-wide fee table. Such fee tables are in effect in other states and, of course, are much below the standard of fees now being paid under the "average minimum" approval standard of the present Workmen's Compensation Act. It may be, also, that absolute free choice will tend to eliminate competition between the present 27 insurance companies and bring about the concentration of all the compensation business under one insurance com-

pany, with whom all would be required to transact business under direct state supervision. There is a possibility that the problem may be solved by the combination of "free choice" under a supervising consultant, agreeable to and appointed by the insurance companies.

While only a few of the 27 insuring companies insist upon their right to "furnish" and name physicians, these few companies insure more than one-half of all the employees covered by the compensation law. Whether this indicates that the few, with most of the business, find "furnishing" physicians more economical than "free choice" is not known. The presumption, however, is that cost is a factor and that the prestige and influence of these companies must be considered when new legislation is proposed. Whatever action the medical men take, appreciation should be shown by all of the broad spirit which has actuated the Industrial Accident Board in dealing with the rights of physicians and surgeons for service rendered injured employees

#### PROGRESS OF POLIOMYELITIS EPIDEMICS.

DURING the past week the epidemics of poliomyelitis in New York and New Jersey have shown definite abatement, whereas those in New England have shown equally definite increase. In New York City the number of cases on September 13 reached a total of 8,614, with 2,151 deaths. In New York State, outside New York City, the number of cases on this date reached a total of 2,690 with 285 deaths. In New Jersey there has been a total of 2,478 cases. There have been 1,149 cases with 288 deaths in Pennsylvania, 122 cases in Chicago and 78 in Toledo. In Illinois, including Chicago, there have been 355 cases; in Minnesota, 142; in Ohio, 94; in Mississippi, 57; in Michigan, 51; and in Iowa, 30.

In New England there have been 11 cases in Maine, 76 in Rhode Island, and 608 in Connecticut. In Massachusetts on September 14 the number of cases reached a total of 239 with 26 deaths since September 1.

At the conference of state and territorial health officials, held on August 17 and 18 at Washington, D. C., in conjunction with the United States Public Health Service, two committees were appointed, one to recommend a uniform method of collecting, recording and transmitting statistics and information regard-

ing the progress and control of the disease. This committee was composed as follows:

Surg. C. H. Lavinder of the Public Health Service, chairman; Dr. W. C. Woodward of the District of Columbia; Dr. C. St. Clair Drake of Illinois; Dr. A. G. Young of Maine, and Surg. J. W. Trask of the Public Health Service.

A national survey at the time of the meeting showed that in the thirty-eight states and territories whose representatives were present, there had been since January 1 of this year a total of 11,717 cases of poliomyelitis, the largest number ever recorded in any epidemic within the same period of time.

The second committee was appointed to propose methods for control of the epidemic, including regulations of transportation. This committee was composed as follows:

Dr. John S. Fulton of Maryland, chairman; Dr. T. D. Tuttle of Washington State; Dr. E. G. Williams of Virginia; Dr. H. H. Brackman of Minnesota and Surg. Charles E. Banks, head of the Public Health Service corps, fighting the disease at New York.

In the weekly bulletin of the United States Public Health Service for September 1 is published the report of this latter committee, whose recommendations are, in part, as follows:

"I. It is the sense of this committee that the first step proper to be taken by a State health authority, believing its territory to be in danger of an invasion by poliomyelitis from another State or part of a State, is to call the attention of the United States Public Health Service to the situation believed to be dangerous, and to request the United States Public Health Service to take whatever steps are necessary to prevent the interstate spread of poliomyelitis.

"II. The necessary steps ordinarily to be taken by the United States Public Health Service in such a contingency are believed to be:

This section describes methods to be observed in investigation of infected areas, notifications of removal, identification of travelers, permits to travel, collection of fees, and certification by private physicians.

"III. The committee supports quarantines by one State against another State, or quarantine by one community against another community in the same State. It is believed that the Federal Government through the United States Public Health Service should perform the duties of notification and certification required in interstate relations, and that the prevalence of poliomyelitis in different States and authorities can and should be made known as between communities. It is believed that unusual prevalence of poliomyelitis in a community should be reported to the Federal Government.

"IV. It is recommended that poliomyelitis should be reported to the Federal Government

local health authorities and to the State health authorities, and that State health authorities make weekly reports to the United States Public Health Service of all cases of poliomyelitis. The United States Public Health Service is asked to furnish general reports weekly.

"V. It is recommended that all persons 16 years old or under, with a clean bill of health, and removing from an infected area or district to another locality, should be kept under medical observation daily for two weeks from the date of the certificate.

"VI. It is believed that the period of isolation of a case of poliomyelitis should be not less than six weeks from date of onset.

"VII. The isolation of cases of poliomyelitis should be stringent isolation of the sick person with attendant or attendants, in a properly screened room or rooms, with disinfection at the bedside of all bodily excretions. Wherever it is possible, the removal of patients to a hospital is greatly to be preferred to isolation in a private house or apartment.

"VIII. In case of death from poliomyelitis the funeral should be strictly private.

"IX. Wherever poliomyelitis is unusually prevalent, assemblages of children in public places should be prohibited.

"X. During unusual prevalence of poliomyelitis, schools should not be opened without thorough medical supervision by a health authority. When schools are opened, beginning should be made with high schools, and proceeding to lower age groups no more rapidly than complete medical examinations can be made.

"XI. Because of the existence of unknown carriers of the infectious virus of poliomyelitis, and because the infectious virus is present in the body discharges of such persons, therefore all measures to prevent contamination by human excreta or other bodily discharges, the suppression of the fly nuisance, prohibition of the common drinking cup, and a general educational campaign for cleanliness and sanitation, with particular instruction of parents and children concerning personal hygiene, especially of the mouth and nose, are urgently recommended."

Attention is further directed to two communications published in the correspondence column of this issue of the JOURNAL, one recording an interesting clinical case of poliomyelitis, the other emphasizing the importance of diagnosis of the lighter forms of this disease. If, as at present supposed, the wide dissemination of poliomyelitis is due to these unrecognized mild cases and to carriers, their study by general practitioners is of especial urgency since upon their recognition and isolation may depend the safeguarding of large numbers and the prevention of the establishment of new foci in uninfected regions.

## AMPUTATION WITHOUT SKIN FLAPS.

A GREAT war is always replete with experience for surgeons and the present one is no exception. Amputations especially are proportionately much more frequent than they are in times of peace, chiefly because of the prevalence of gangrene, due to the necessity of leaving badly wounded men without surgical aid for days at a time. It is natural then that the technic of amputation should receive careful attention; many surgeons, for instance, advocate plane section on the battle field or at the base hospital with a secondary operation along conventional lines later on when the patient has been removed from the front. The advantages alleged for this procedure are quickness and ease of performance and the avoidance of pockets to fill up with pus. Against this method is urged the experience that soldiers refuse a secondary operation and thus are left with a surgically bad stump.

Another method, which would hardly be sanctioned in normal times, is that of flapless amputation. Writing in the *British Medical Journal* for April, Dr. Fitzmaurice-Kelly describes his experience with this method which he heartily favors. He claims that it saves the maximum length of limb and, in many cases, life itself. He considers this form of treatment absolutely indicated in gangrene, and the method of choice in certain cases of compound and comminuted fractures and in multiple wounds. In cases of gangrene, he says, the entire skin of the limb appears to be unhealthy and when flaps are cut these invariably slough and start a gangrenous process in the stump. On the other hand, if a flapless amputation be done, section can be made just above the gangrenous area, as low as, or lower in fact than, the point where the skin flap is usually started.

Fitzmaurice-Kelly states that there is practically no secondary hemorrhage with this method, that it arrests the spread of infection, and that it can often be done where no other method is possible. The chief disadvantages appear to be the necessity of a second operation, the obvious discomfort and danger of a large, open, granulating surface and the occasional development of ascending neuritis. Even if these objections be valid, the advantages would seem to outweigh them, especially in view of the lack of success of the classical amputation in gangrene so far.

## THE RECORD OF A MEDICAL CLASS.

We have recently received from the secretary of the class of 1911 of the Harvard Medical School a class report, the first which this class has issued. The publication of such reports has not been usual with medical, as it is with academic classes, and its appearance is a matter of considerable interest not only to friends of members, but to those who are glad to watch the progress of their junior colleagues in medicine. There is an excellent preface by the secretary, a statement of the class finances, a class directory, four pages of class statistics and a report of the class dinner held this year. The remainder of the volume consists of a series of brief sketches of the lives of the members, eighty-nine in number. At the close is a map of the United States representing the geographical distribution of the class in practice. Thirty-eight are in Boston or in its vicinity, one is in China, and the remainder are scattered in the north and middle West and along the Pacific Coast. The cordial appreciation and congratulations of the JOURNAL are extended to the class upon this record of its work.

## MEDICAL NOTES.

**THE NEW YORK MORTALITY RATE.**—During the past week one hundred and fifty-two deaths were reported as due to infantile paralysis, as compared with 209 during the previous week and 301 for the week ending August 12th. The epidemic is evidently fast burning itself out. There seems to be every prospect of conditions again reaching normal within the next two weeks. It is encouraging also to note that the mortality of the contagious and diarrhoeal diseases continues to remain lower than during last year. The mortality of the following diseases was lower during the past week than during the corresponding week of last year: measles, whooping cough, typhoid fever, cerebro-spinal meningitis, diarrhoeal diseases, pulmonary tuberculosis and diseases of the nervous system. The total number of deaths reported during the week was 1,388 as compared with 1,515 reported during the previous week, the death rate for the past week being 12.96, as against 14.13 for the week ending August 26th. The death rate for the first thirty-six weeks of 1916 was 14.51 and the death rate for the corresponding period last year, 14.42. In commenting on the figures, Commissioner Emerson pointed out that there was every prospect of having a lower general death rate in New York City this year than ever before. "In view of the outbreak of grip last January, and especially in

view of the 2,000 deaths from infantile paralysis this summer, this is a remarkable showing."

**PREVALENCE OF MALARIA, MENINGITIS, PELLAGRA, SMALLPOX AND TYPHOID FEVER.**—The weekly report of the United States Public Health Service for September 1, states that during the month of July, 1916, there were in Mississippi 21,091 cases of malaria, 1,047 of pellagra and 1,205 of typhoid fever. In Virginia during the same period there were 982 cases of malaria, 16 of cerebro-spinal meningitis, 73 of pellagra and 699 of typhoid. There were 18 cases of meningitis in Ohio, 94 cases of smallpox and 319 of typhoid. There were 85 cases of smallpox in Michigan and 223 of typhoid each in Indiana and Kansas.

**A SULU HOSPITAL SHIP.**—Report from New York on August 17 states that the Philippine Government, in cooperation with the International Health Board of the Rockefeller Foundation, is to send a hospital ship to the Sulu archipelago. These islands are inhabited by about 200,000 Moros and other savage tribes. It is planned to maintain the service of the hospital ship for at least five years.

**CHANGES IN DRUG PRICES.**—Report from New York on September 9 records a few recent changes in the cost of drugs, especially an increase in the price of glycerin.

"A gradual advance is taking place owing to the ever-strengthening position of the crude and dynamite grades which have been practically withdrawn from sale. Another advance of 1 to 1½ cents per pound was named in the chemically pure grades yesterday, the new offering price in drums being 42½ to 43½ cents.

Selling agents for quicksilver have reduced their prices \$4 to \$76 per flask of 75 pounds. This decline is attributed to the favorable settlement of the railway strike.

Peppermint oil continues to advance, \$2.25 being now inside for bulk. An advance to \$1.75 @ \$1.80 has taken place in spearmint in sympathy with the rise in mint oil. Newfoundland cod liver oil is reported materially weaker at \$72 per 30-gallon barrels, a decline of \$3.

## EUROPEAN WAR NOTES.

**PERSONNEL OF HARVARD UNIT.** In the issue of the JOURNAL for August 21 we noted the sailing of another reinforcement for the Harvard Surgical Unit at the front in France. The medical personnel of this unit was as follows:

Dr. Daniel Fiske Jones, Boston; Dr. Lucius C. Kingman, Providence, R. I.; Dr. Samuel W. Jackson, Walldoboro, Me.; Dr. H. and W. Stevens, Cranberry Island, Me.; Dr. Harlow C. Irwin, Wilkesboro, N. C.; Dr. Robert H. Vane, Boston; Dr. Benjamin H. Allen, Ipswich, Mass.; Paul D. White, Boston; Dr. George P. D. Allen,

Boston; Dr. Orland F. Montgomery, Rangeley Lake, Me.; Dr. William A. Frontz, Baltimore.

**APPEAL FOR SERBIAN RELIEF.**—A committee authorized by the French and Serbian Governments, and approved by the Serbian Relief Society, is raising funds to meet the urgent need of support for field hospitals among the Serbian army in Saloniki. This committee has recently issued an appeal based upon the following letter recently received from a French woman in Saloniki.

"Our friend G— and I were considering yesterday in what way we could help the Serbian army, which is now reconstructed and stationed here. . . . They have nothing—less than nothing—and must necessarily have recourse to the French hospitals. It is because of this that I have in my charge the care of the Serbian officers and soldiers. I talked yesterday with the chiefs of their medical service, and their anguish was great, for they have nothing,—neither hospitals, nor ambulances, nor transports, nor automobiles,—and in their intense desire to be again at the frontier of their own country they are asking each other how they will be able to transport their wounded and sick.

England and France already have a heavy burden. The French hospitals here are far from sufficient, and we need so many beds. The personnel is good, but the material necessities are lacking, both beds and ambulances.

I am head nurse in the largest quarantine hospital here (1500 beds), set apart for contagious diseases. We are working day and night now, and the heat is overwhelming, and all the diseases that we dread are spread by it. The overcrowding is great and the Serbian soldiers, who have only a few beds, are scattered here and there.

It is necessary to see this to feel all the horror of it. Even now we are put to the test by the sickness alone of the Allied armies. What will it be when they start fighting?

Please forgive my importunity, for now anything seems permissible and your country is such an immense storehouse and her generosity is incomparable. Consider that all our gold and all our reserve stores have been turned into ammunition, cannon and bullets. Though we are now in the middle of summer the third winter is approaching, bringing with it new sufferings."

Subscriptions towards the maintenance of a hospital for the Serbian army should be sent to the Franco-Serbian Field Hospital of America, 17 West 30th Street, New York City.

**GERMAN ARMY DENTISTRY.**—In the spring of 1916, a meeting of German civilian surgeons and dentists was held in Berlin, at which Surgeon-General Schultzen presented a statement of the organization and work of the German

Army dental service. This statement is abstracted as follows in a recent issue of the *British Medical Journal*:—"The work fell into two main divisions—the treatment of wounds of the jaw, which was the more important, and the everyday treatment of soldiers' teeth, including the making and fitting of artificial teeth, to render the men fit for active service or employment on war duties. The incidence of wounds of the jaw had, he said, far exceeded expectations, with the result that five dentists had to be attached to each army corps, although, under an arrangement made in 1907, only one dentist was provided for each. Dentists were appointed to military hospitals where adequate facilities were provided for skilled work, and were employed also to a certain extent nearer the firing line, when the fighting assumed a stationary character. In fracture of the jaw, the primary object of the dentist was to immobilize the fragments in order that the patient might be sent on at once to a special jaw hospital at home, where extensive operations could be undertaken. About 1,000 dentists were employed by the army on the lines of communication and at home. The organization had worked smoothly. It had been hoped that, owing to the supervision and treatment of school children's teeth, the teeth of the recruit would be found on the whole to be sound. But between the school age and the military age there was evidently time enough for neglect of the teeth to provide plenty of work for the army dentist."

**WAR RELIEF FUNDS.**—On September 15 the totals of the principal New England relief funds for the European War reached the following amounts:—

Secours National Fund	\$210,354.17
French Wounded Fund	118,574.56
French Orphanage Fund	61,875.93
Belgian Tobacco Fund	58,650.00
Surgical Dressings Fund	46,322.37
Prince of Wales Fund	14,731.92

#### MEXICAN NOTES.

**HYGIENIC CONDITIONS IN MEXICO.**—In last week's issue of the *JOURNAL* we noted the relatively low disease and death rates among the United States troops at the Mexican frontier. Report from field headquarters of the American Punitive Expedition in Mexico on August 23, states that during the past five months the members of this expedition have suffered only six deaths from disease. The present sick rate is 1.5, which would be increased to 2.5 if a number of patients treated at the base hospital were added to those in the field. There has been a good deal of amebic dysentery among the soldiers, which was controlled by means of chloride disinfection of the water supply.

On August 23, Dr. Thomas Darlington of New York, representing the National Civic Federa-

tion, made the following report of his recent tour of inspection among the troops at the frontier and in Mexico:

"I have inspected the base hospitals at San Antonio, El Paso, Nogales and Douglas, and have seen the troops in the field. I spent four days at Colona Dublan, headquarters of General Pershing's forces. The camp is most interesting. I don't suppose there will ever be another one like it. To be sure, conditions are not ideal; the flies are pretty thick, but the point is, in Mexico, as along the Border, army officials have done their best for the comfort and health of the men."

There are, at present, sixteen hospitals of the War Department established along the Mexican border. These are already equipped to accommodate 2,500 patients and when completed will have a capacity of 4,500.

**MASSACHUSETTS VOLUNTEER AID FUND.**—On September 16, the total of the Massachusetts Volunteer Aid Association fund for the relief of families of Massachusetts troops at the Mexican frontier reached the amount of \$75,990.15.

#### BOSTON AND NEW ENGLAND.

**WORK AND NEEDS OF CARNEY HOSPITAL.**—A recently published fifty-second annual report of the Carney Hospital records the work and progress of that institution during the past year.

"The number of patients admitted during the year was 3,756; the number discharged, 3,589; died, 153; remaining, 132. The expenses for charity patients were \$16,752.80.

"The Sisters of Charity of St. Vincent de Paul in their report call attention to the desirability of the erection of the south wing, intended in the original plan, but held back because of inadequate means.

"Eighteen cases in the out-patient department and three in the hospital were treated in the radium therapy clinic from its beginning, Dec. 22, 1915, to April 1, 1916.

"Of it the Sisters say: 'Among the movements of 1915 which have been of great interest in bringing us new aids in our efforts to better the condition of suffering humanity, the most important is the gift of radium by Professor M. Douglas Flattery for the establishment of a clinic. Radium treatment, beneficial in many conditions, is rapidly being granted priority over other treatments in the cure of malignant disease.'

"Another contemplated improvement is a Nurses' Home, to be erected opposite the hospital on the site of the three small buildings now occupied by the nurses, yet affording insufficient accommodations."

Dr William H. Devine, president of the staff, calls attention also to the desirability of adding a solarium to the equipment of the Hospital. This could be done by building a series of piazzas

on the south side of the Hospital, each piazza to accommodate thirty patients.

**FLOATING HOSPITAL'S EXCHANGE.**—On a recent trip of the Floating Hospital, stop was made at Bumpkin's Island. The doctors and nurses of the Burrage Hospital and those of the Floating Hospital exchanged places during the stop, those of the Floating Hospital taking charge of the Burrage Hospital and giving up the care of the boat to the doctors and nurses of the island hospital. The Long Island Hospital has invited the Floating Hospital to make a similar exchange with its institution.

**THE WEEK'S DEATH RATE IN BOSTON.**—During the week ending Sept. 16, 1916, there were 216 deaths reported, with a rate of 14.81 per 1000 population, as compared with 234 and a rate of 16.30 for the corresponding week of last year. There were 50 deaths under 1 year, as compared with 57 last year, and 56 deaths over 60 years of age, against 61 last year.

During the week the number of cases of principal reportable diseases were: diphtheria, 29; scarlet fever, 16; whooping cough, 13; measles, 20; typhoid fever, 11; tuberculosis, 54.

Included in the above were the following cases of non-residents: diphtheria, 12; scarlet fever, 1; tuberculosis, 8.

Total deaths from these diseases were: diphtheria, 1; measles, 2; tuberculosis, 20; whooping cough, 2.

Included in the above were the following deaths of non-residents: tuberculosis, 3; whooping cough, 1.

#### Obituaries.

##### EUGENE POTTER STONE, M.D.

DR. EUGENE POTTER STONE, U.S.N., RETIRED, died at North Sutton, N. H., on September 5, 1916. He was a native of Boston and graduated from Harvard Medical School in 1884, entering the navy very soon, and spending his life in the service until he was retired five years ago, because of illness. Just previous to his retirement he was in charge of the naval hospital at Manila. From 1884 until 1890 he was a Fellow of the Massachusetts Medical Society. He is survived by his widow, who was Miss Margaret Grant of Brookline, and by two sons, one of them a student at Harvard Medical School.

##### REUBEN WILLIS, M.D.

DR. REUBEN WILLIS, of South Scituate, Mass., died at the Robert Barr Bridge of Heart Disease, Boston, Mass., September 6, 1916, at the age of 64 years, after a hemorrhage, aged 7 years. He was born in Belchertown, Mass., Sept. 10, 1851, and was the son of Jacob and Sarah (Frost) Willis, and was a private physician in South Scituate, Mass.

Volunteers, in 1861, and saw service in the attack on Roanoke Island and at the Battle of Newbern, being mustered out November 23, 1863. He was graduated from Harvard Medical School in 1867, and practised in Somerville, where he was a member of the staff of the Somerville Hospital. He joined the Massachusetts Medical Society in 1870, and was retired in 1908. He is survived by his widow, who was Miss Eugenia Stowe of Arlington, and by one daughter.

### Miscellany.

#### THE LILIENFELD X-RAY TUBE.\*

IN a recent issue of the *Scientific American* is published a summary of an article in *Die Umschau*, describing a new type of tube for the production of x-rays, named after its inventor, Lilienfeld. Under ordinary circumstances the rays are given off by the metal surface of the anti-cathode under the influence of a bombardment of cathode rays thrown out from the negative pole of a Crookes tube when the latter is discharged by a high tension current.

"The more nearly perfect the vacuum in the tube, the higher tension required for the discharge, and the 'stronger,' or more penetrating, the resulting Roentgen rays. 'Strong' tubes, giving strong rays, are used for taking shadowgraphs of the denser, bony parts of the body; weaker ones, for the less dense tissues. In order to be equipped to meet any case that might arise, the surgeon must keep on hand an array of tubes of different strengths. Nor is that the only disadvantage of the tubes in ordinary use. For any given tube a certain fixed current is proper; and if a stronger (or weaker) current should by accident be used, air passes out (or in) through the walls of the tube and strengthens (or weakens) the vacuum, and hence the tube. To be sure, the original degree of hardness can be restored, but only by a long and complicated process.

The Lilienfeld tube is free from these disadvantages. The vacuum is practically perfect; so it can be used without special preparation. Its operation involves rather more complicated theory than does that of the ordinary tube, but no more care or attention is demanded of the operator. The anti-cathode, which also serves as positive pole, projects from the top. The long narrow central tube contains the Roentgen cathode, bored from end to end parallel to the axis of the tube. Between the negative pole, situated in the obliquely projecting tube below, and the anti-cathode, a high tension is maintained. The discharge of cathode rays is not induced by this current, but takes place in the filament in the lower bulb, which is made incandescent by an auxiliary current. These rays are driven violently upward through the boring

by a high-tension current arranged for the purpose; and their passage making the upper part of the tube conductive, a strong Roentgen discharge then takes place. This accelerates the cathode rays even more, and they fall upon the surface of the anti-cathode with great force, causing the latter to give off the desired rays.

If the current in the auxiliary circuit is increased, more cathode rays will be thrown out by the filament, the tube will conduct better, and the Roentgen rays will be stronger. So that by the manipulation of a resistance switch in the auxiliary circuit, Roentgen rays of any desired strengths may be instantaneously produced, one after another, and employed successively in photographing regions of varying permeability. The extremely high vacuum excludes the possibility of accidental strengthening of the rays through loss of air from the tube. Again, in the new model the primary high tension current does not itself have to make this vacuum conductive, since the filament sends its cathode rays through the entire tube. And on account of the small bore, these fall upon the anti-cathode in a very close, dense bundle, and produce there a tiny bright spot, from which the Roentgen rays are given off sideways, to the left. The close approach of this source of the rays to a single point insures a sharp and finely differentiated negative. In the old apparatus, on the other hand, some of the cathode rays fell upon the glass walls of the tube, heating them to incandescence, so that there was a certain loss of power. Furthermore, the life of the rays is considerably greater in this new device than in the old, making possible longer exposures and photographing of regions heretofore impermeable.

Most notable among the advantages of this new apparatus is the way in which it reduces Roentgen photography to a mechanical operation. By mere adjustment of an indicator on a scale the current is so regulated as to give a sheaf of Roentgen rays of proper strength.

The chief advantages of the Coolidge tube have been experienced in the field of Roentgen therapy; those of the Lilienfeld tube promise to affect rather the field of skiagraphy. Its value and merits must await the determination of experience.

#### DECLINING BIRTH RATES.

IN a recent number of the *Journal of State Medicine*, Sir Thomas Oliver, M.D., of the University of Durham, writes an interesting article on the subject of declining birth rates. He regards as primary influencing causes the emancipation of women and the great change in living conditions during recent years. He states:

"The increasing absorption of young women into spheres of commercial and industrial activity, while tending to lighten the bur-

den of parental obligation, is creating problems which in their final issue concern the future of the race. As effects of the withdrawal of female life into industry, mention may be made of the weakening of the home instincts, a love of independence, and a growing taste for pleasure and excitement, so that if marriage is entered upon, there is a growing unwillingness to accept the duties and responsibilities of motherhood."

During the past thirty years the greatest decline in birth rate among leading countries was in England, which declined 25%. Russia had the least decline, 1%. Between these extremes come Austria, Denmark and Switzerland with 12%, Italy and Finland with 13%, Sweden with 14%, Norway with 16%, Germany with 18%, Holland with 19%, and Belgium and France with 21%. For comparison, the decline in Boston for the past twenty years is 8%. As to increase in population since the Battle of Waterloo, Oliver makes the statement that France has increased one third, Great Britain and Ireland have doubled in numbers, Germany has quadrupled and Finland has increased three times. Italy stands at one-half more and Austria one and one-half. The fluctuations of numbers of inhabitants in Italy are given with Fries as an authority. In 220 B.C. the population numbered twenty-two million, by 2 A.D. it was less than half this figure and decreased to five millions two centuries later. At the beginning of the second Punic war there were 270,000 citizens fit to bear arms, and at the time of Augustus, there was doubt whether 45,000 men could be raised. This reduction took place during a long period of peace, and is an example of a nation which has attained a high position in civilization, and then thrown aside those implements which have enabled her to gain this position.

"A nation's worth," writes Dr. Oliver, "like a nation's hope, rests not necessarily on one class of society, but upon the members of all classes who are thrifty, who are leading normal lives and who are discharging simple duties to the family and to the state."

In this connection it is interesting to note the statements of Professor Walter F. Willeox of Cornell, in the March number of the *Journal of Heredity*. In regard to the decline of both the death and birth rate, he believes that the death rate can and it must be controlled by the education of the people. He does not regard this decline of births, however, as an unmixed evil, for he states that had the birth rate not diminished, the population of Europe would now, but for the war, be increasing faster than the wealth or food supply could maintain it. The unfortunate aspect of the situation is that those strains best qualified to perpetuate themselves, such as college graduates and native American stock, are classes which contribute most to the

declining rate. As a striking example of the present rate of declination of births, he calculates, using the ratio of children to women of child-bearing age, that, should conditions remain precisely the same, in a century and a half there would be no children born. He does not presume, of course, that conditions will remain the same, but makes the statement as an argument for proper consideration of a significant trend of civilization.

## Correspondence.

### HOSPITAL AND GENERAL PRACTITIONER

Mr. Editor:—

One has heard of late statements *ad nauseam* as to the desirability of group-practices, as to the preeminence of modern hospital methods, and the utter futility of the practitioner. Not unnaturally the practitioner has "come back" in rebuttal. But the statements in rebuttal have been protests as to the method of presentation; and as to that only. It is not really important whether photographs of the disputant's family life accompany the article or not; the question is, at the long end of it all, whether he is right or wrong.

My quarrel is with the alleged facts that have been so gaily assumed as premises. It has been asserted (and loudly) that hospitals do work far better than the general practitioner can do. Case for case in the whole community, this may be true. I doubt it a bit, but hope I am wrong, as I try to be proud of my own hospital service. But if this is true, why is it true? Is it because of laboratory facilities, as we are so often told by a man who only recently characterized all urine analyses as useless or needless? Probably not.

Probably if it is true that the hospitals (the public ones) do better work, it is because they make a sincere and rather successful effort to pick the best men in the community for their staff positions. These men work along, year after year, recognizing that the house officer in training is not half so good an assistant as his hospital predecessor (now the surgeon's private assistant); recognizing that Dr. X could, and would, take far better bismuth plates in his own x-ray plant, and that the plates would be filed, not lost; recognizing that nurses in training are not so good as they will be after they are trained; knowing that the externs eke out in a way that would not "get by" outside, but realizing that these folk must learn, while the "Visiting" does the best he can under the handicap.

They do this work partly because of tradition and a vague sense of public duty; partly because of the constant intimate contact with their peers, which so much makes for sanity and balance; partly because the vast experience gained in what we may call the loose wholesale business of a hospital is a great help toward a perspective, hardly to be gained by the more careful and detailed work of a private practice, which must, in the nature of things, be relatively small in those years in which a man's maximum hospital work is done.

After this period, he goes on as with his other fixed habit. If the hospitals turn out better work, it is because they have the best men; not because the hospital system is ideal.

Just now a nation-wide movement of standardization is showing some signs of success. This is not because the country is becoming more homogeneous, but because we have had a chance for a few years to rate efficiency with regard to the treatment of

accidents. Do the big hospitals show up in the lead? I throw not; very much not!

Best of all are the "company hospitals" of the big industrial plants. Worst of all is the untrained practitioner; poorly equipped because of poor pay. So far as I can get the facts, most of the reasonably successful practitioners show up about level with the good hospitals in results.

Let us not forget that the "G. I." has an x-ray man who does better work in the office afternoons than at the hospital of a morning; that he can always get interested advice from a medical or surgical colleague, or a nerve sharp, or a skin specialist, or what not, at any time, even for the patient who cannot pay a cent, and that this colleague will do better work on a case so referred than he does (however good his intentions) on a routine case pushed into the routine of his clinic.

One cannot quite organize any professional service; least of all that service of medicine which has from time immemorial been personal, altruistic and interested.

The doctor must be paid; he spends like another; wants as much money, but after all you cannot quite buy a doctor! His best work is where his heart is, and pay has little to do with it.

I am afraid that as time goes on, there is danger that medical care of the citizen is going to become a function of the State, but there is some comfort in the fact that we of this generation are not likely to live to see this development interfere seriously with our own work in the profession we have grown up in.

One other point, and I am done.

In this social or sociological scheming for the uprooting of medical practice, much has been made of the successful experiments of certain universities in the care of their students. Does it not occur instantly to any thinking man, that what can be done—has been done—at certain Western universities, namely, care at \$5.00 (or whatever it may not up) for the year, is absolutely valueless in arguing as to the medical care of a mixed community? Not only are the students at the age of maximum vigor, maximum interest in active affairs, minimum morbidity, but they are a picked class as well; the very best of our population. More than this, they are exempt from want, exempt from the strain and risk of industry, and exempt (or nearly so) from the great load of alcoholism and social vice. What can one argue from such a community as to what can be done in one of our big cities?

If we are to plan for the "socialization" of our profession, is it not time for us to look to men who can think in broad terms; who are fit to be leaders in a broad consideration—not of theories but of conditions, as they are; who can plan for the future, not for Utopia?

Changes in medical practice are sure to come; probably rather rapidly. Should we not plan to meet them by consideration of facts, as they are, not as they might be?

Very truly yours,

FREDERIC J. CORTON, M.D.

Boston, August 9, 1916.

P. S.: By the way, there may be some of your readers who mistake all this recent stuff for original thinking.

They should be disillusioned and referred to the long prologue of "The Doctor's Dilemma" by a wonderfully whimsical, clever, witty and mainly wise Irishman, named Shaw, who writes wonderful English to express rare sense and rarer nonsense. Perhaps he is right; perhaps (as I think "mine own self" a half right; but Bernard Shaw did the only real thinking involved in this medico-sociological problem.

This relation of thought to headlines seems not unusual.

F. J. C.

## BETTER DOCTORING FOR LESS MONEY.

Boston, Mass., Aug. 14, 1916.

Mr. Editor: I have been interested in the discussion in your columns of "Better Doctoring for Less Money," and have, therefore, read with care that contribution. I am reminded of the homely saying of one of our native philosophers: "It's better not to know so much than it is to know so many things that ain't so."

It must be a matter of regret that the writer of the article in question chose to express his opinion in such an infelicitous manner. Here and there is a suggestion of irony, to be sure, as in "the state of things which I have described—I believe without exaggeration." But whether it be satire or something else, it is to be taken seriously and it is a fair question to ask what the author is trying to say.

It is unfortunate that attention has been so diverted by the misrepresentation on the part of the author, perhaps *gaucherie* is a more accurate term, that his main point, as I see it, seems to have been missed by some of the critics.

The writer believes, as I understand him, that co-operation among physicians, by the group system, in connection with hospitals, will solve the problem of bringing to all who are sick the best medical art of today at a cost which any can pay. Stated thus concisely, it is easy to see that not all can have the best, and the problem is not the same in rural as in the urban communities.

There is some such problem before the medical profession today. Its solution is not yet clear. Perhaps the group system, in reality widely spread at present, may be of some assistance if it is more formally and extensively applied, and linked with hospitals. That this alone will suffice is questionable.

Now many other problems are touched upon in the original article and in the rejoinders. It would take too much of your time for me to specify all the errors, inaccuracies and misrepresentations. Scarcely a paragraph is above criticism. The comparison of students, picked young men and women, with the clientele of a general practitioner is illuminating. I am inclined to think that at a university clinic there would be little material for the departments of obstetrics, gynecology, pediatrics and genito-urinary diseases, for example, which constitute an important part of the interests of the man in general practice. Then, too, the diseases of the "degenerative" type, common after fifty, one would hardly expect to see. Is it true, I wonder, that at the University of California suspected early disease is real, at Harvard imaginary?

In the closing section, on the financial temptations of doctors in private practice, the author has demeaned himself unworthily. His arraignment of the medical profession is unjust. Is it not more nearly true to say that it is one of the glories of the medical profession that physicians spend their lives in preventing disease and curing the sick, trying to accomplish that which, if successful, would take away their livelihood?

But my object in writing is to call attention to the fact that we seem to be forgetting ourselves. Why this acrimony of discussion? The specialist is not a recent development. Before the times of the Father of Medicine, there were specialists among the Egyptians, and probably there will be specialists for some time to come. I am inclined to think the general practitioner will fortunately always be with us, not however, because he is poor. It will be a sorry day when society is so organized that there is no longer a place for such a man as the Doctor of the Old School.

We sometimes think of the specialist as one who charges special, that is high prices, not one who, having special knowledge and skill, renders special service in the art of medicine. It is the specialist on whom chiefly falls the burden of advancing knowledge

in both the art and the science of medicine, and his is the corresponding joy. This duty of the specialist is too often forgotten.

There are faults on the part of some specialists and on the part of some general practitioners. Whether the faults will be affected by the new era I do not know. Some physicians in general practice are ignorant, unscrupulous, dishonest, criminal. Well, so are some specialists. So are some lawyers. Some men and some women are unfaithful to their marriage vows. Shall therefore the marriage vows be relegated to the limbo of outgrown and harmful superstitions?

The problems arising from the growth of specialism, the progress in medical knowledge, the concentration of population in large urban communities, and the tendency toward socialization of many activities within the state, are problems which concern all of us, which we must all face and to solve which we must all do our part.

Efficiency is the cry of today. It is not new. "Whatsoever thy hand findeth to do, do it with thy might, for there is no work nor device nor knowledge nor wisdom in the grave where thou goest." But efficiency in itself is not what we want. A machine that makes an automobile a minute may be efficient in one sense of the word, but if it is telescopes that are wanted, "it cumbereth the ground." So the general practitioner is relatively inefficient in making very exact physical diagnoses, dispensing drugs, keeping elaborate records, compiling statistics, even in performing delicate and difficult operations, of which there are really some in modern surgery. But we find him very efficient in ministering to some of the needs of his people, for these often love their family doctor and look upon him as their friend. I wonder at times if a reason why some of the members of the medical profession are not looked up to as were our grandfathers, is not because we have not as much real manhood as they possessed. We know more about leucocytes and phagocytes, toxins and antitoxins, Widal's and Wassermann's, but are ignorant of the weightier matters of the law which made them towers of strength in their communities.

I do not mean even to suggest the solution of the many problems confronting the medical profession today. The solution is not easy. I am quite sure, however, that it is not true, as the writer of a Question of Medical Ethics says, "if we worked in harmony more and talked harmony less, advance in medical progress would be assured and unobstructed." For lack of harmony is not the only obstruction to advance in medical progress. But it is true that when "we put aside petty jealousies and work together for the common good," we have made a beginning in the right spirit, the spirit which does actuate most of the men in the profession. And medicine is a profession; it is not an industry or a trade. But to this right spirit must be added intelligence, honesty, love of justice, forbearance, and loyalty to high ideals, which means determination to make them real.

Yours very truly,  
STEPHEN RUSHMORE, M.D.

## THE FUTURE OF BLINDED SOLDIERS

(From Our Special Foreign Correspondent.)

LONDON, JULY 16, 1916

### ST. DUNSTAN'S HOSTEL FOR BLINDED SOLDIERS AND SAILORS.

Mr. Editor: A great work is being carried on by the National Institute for the Blind. Sir Arthur Pearson, President and Honorary Treasurer of the Society, is himself blind, and has organized a "house of good comfort" for blinded sailors and soldiers. A house and extensive grounds in Regent's Park were

turned over to the institute through the generosity of Mr. Otto Kahn, an American, and in March, 1915, these premises became St. Dunstan's Institute for the Blinded Soldiers and Sailors.

At the end of the first year, in March, 1916, there were at the hostel, or in the annexes at the sea-shore, 140 non-commissioned officers and men. St. Dunstan's is a "workshop of darkness," differing from other institutes for the blind in that those who enter were, not many months before, strong men, possessed of their full powers.

As I approached Regent's Park I met two blind men. They had come to a crossing on a busy street and hesitated. A passerby stepped up and piloted them across and the two passed on down the side-walk as though much at home. I entered the park and turned up the driveway to St. Dunstan's. There seemed to be no able-bodied men about, but one grows used to that in these times. Even the lodge-keeper was one-eyed. The hostel was apparently filled with young ladies in Red Cross uniforms or dressed in simple white. None of the blinded was in sight, but as I walked out to the gardens one entered whistling cheerily. He passed through the room, following the strip of carpet laid as a pathway through the building. A young lady acted as my guide, and we proceeded to the workshops scattered about on the lawn, which sloped gently down to Regent's Park Lake. We entered a hut where a dozen or more men were being taught to read and write Braille, which, I believe, they pick up in a surprisingly short time. The alphabet is the same as that used in America, but the abbreviations are quite different. They write with machines resembling small, two-faced typewriters, which punch out the letters on strips of stiff paper. The teachers are women who come in each morning for this voluntary work. A small class was learning typewriting, and I was told that a number had secured good positions as stenographers.

At the sound of my guide's voice several of the men cried out, "Oh, Miss , will you save me a dance tonight?" It seems that, in addition to other entertainments, dances are held once or twice a week, and all the men are instructed in the terpsichorean art.

We passed an open window and stopped to look in on a group of men gathered about a table. One was reciting an accurate description of the surfaces and borders of the clavicle, while the others followed by fingering specimens of the bone. This was an anatomy class for those who wished to become masseurs. The blind have had considerable success with massage. One of the men from St. Dunstan's recently took the first place in the examinations given by the Incorporated Society of Trained Masseurs, against 180 competitors. Others are doing massage now in military and civilian hospitals. We entered the workshops. Here was a perfect babel of noise. Singing and whistling were punctuated by the rapping of many hammers. One section was making shoes, and very good work they did. Another was carpentering, and their instructor, also blind, passed by my from bench to bench. The joints they made were excellent. Some worked at mats, others wore hats, coats or nets. I was told that a number had left the telephony, and were now doing the work of contractors in a satisfactory manner. Others had become as trained gardeners.

The institute publishes, month for the blind and also a weekly edition of the *Daily Mail* that, due to the generosity of Lord Northcliffe, the men seemed surprisingly busy and happy. The fact, one might travel a long way before finding a substitute of this nature which is pervaded with such a cheerful atmosphere. Not the whole day is spent in work. In each afternoon they take a tea-break, relax, and many spend their time reading or conversing.

ST. GEORGE'S, JULY 16, 1916.  
W. G. P.

## LIGHTER FORMS OF POLIOMYELITIS.

*Mr. Editor:—*

Several cases that have come under my observation during the past two or three weeks lead me to the inference that some of the men in a position of more or less official authority in this State in connection with the present epidemic of poliomyelitis are not conversant with the lighter forms of this disease. If we may reason from analogy with other infectious diseases, it would seem as important to recognize and isolate the light forms of poliomyelitis as it is to subject the more pronounced cases to a strict quarantine. The failure to do so offers a menace to the community really greater than the unrestricted freedom of a well pronounced instance of the disease, for in the latter instance a brief period of relative isolation is naturally enforced by the victim's more or less helpless condition.

The fact that seems not recognized by those responsible for the enforcement of quarantine is that absolute paralysis of muscles or muscle groups is not necessary for the diagnosis of anterior poliomyelitis. Many years of observation, previous to the present epidemic, at a large clinic in this city where many cases of this disease are seen every year, has demonstrated the fact that instances occur in which after an onset of typical character, with vomiting, fever, constipation and malaise, the child is left without absolute paralysis of any muscle or muscle-group, but with relative weakness of some muscle or group of muscles, and with loss of the deep tendon reflexes corresponding to or in the vicinity of the parietic muscles.

These cases must be considered as instances of anterior poliomyelitis. No other diagnosis is justified, and, so far as we know, the victim of such a symptom-complex is just as much a menace to the community as the victim with complete paralysis of an extremity. The extent and severity of the disease in any one individual is probably a matter largely of relative individual immunity. If we admit at all the contagiousness of this disease, we must recognize that, as in the case of diphtheria, a light instance in one child may transmit to some other child a more malignant type of the disease.

Physicians in responsible positions in hospitals or in health departments may be pardoned in failing to recognize abortive forms of this affection without sequelae, but it does not seem so excusable to ignore, during an epidemic, cases with conspicuous onset followed by the residual of relative muscular weakness and abolition of the deep tendon reflexes, especially when this is conspicuous in one limb when compared with perfectly normal conditions in the opposite extremity.

Another variety of this disease that does not appear to be readily recognized is that which takes the form of acute encephalitis without nuclear involvement, either bulbar or spinal. I had thought that the long disputed claims of Strumpell had for some years been recognized as valid, but I was surprised to find recently that reluctance existed in a certain Boston hospital to accepting the identity of the two forms of infection, nuclear and cerebral. Not only do we have cases, during epidemics of anterior poliomyelitis, with purely cerebral symptoms, but such instances may on autopsy present no macroscopic explanation of the cause of the symptoms or the reason for the fatal termination, these being revealed only by careful and extended microscopic examination. These are instances in which the process is of focal character, and more or less limited in extent. They may not be accompanied by any localizing symptoms during life, but they are often characterized by hemiplegia or monoplegia, of course of the spastic type. They are frequently of very acute onset with a sharp rise of temperature, which, however, does not subsequently present any particular curve, and often soon falls to or near the normal level. In children, the convulsions that sometimes accompany the affection are

frequently attributed to errors in diet or to some such irrelevant cause.

Under present circumstances I feel that attention should be called to the above facts, and I trust you will lend your columns to their publication.

Very sincerely yours,

ARTHUR W. FAIRBANKS, M.D.

## A CASE OF POLIOMYELITIS.

*Mr. Editor:—*

The following brief account of a case of acute anterior poliomyelitis may be of interest on account of the age of the patient.

A man, sixty years and eleven months of age, awoke Thursday morning, Aug. 17, at about five o'clock, feeling sick. He ate little breakfast, but went to his work as a carpenter. He had such severe pain in his shoulder blades, shoulders and extending down the outer side of his upper arms and he had to leave work and go home at eleven o'clock. He was very restless during the afternoon, and sent for me in the early evening. The pain, which he described as "horrible," was not affected by movements of his arms, which he could make freely in all directions. There was a slight retraction of the head as he lay in bed, and some resistance to flexion of the neck, although he could rotate the head without difficulty. He was extremely restless, continually getting in and out of bed, and occasionally walking to the bathroom. The temperature was 101°; pulse, 90.

My suspicion was aroused by the severity of the pain, the indefiniteness of its location, and the fact that it was not affected by movements; by the slight rigidity of the neck, and the rise of temperature. During the next day he was much as he had been on the day before, although he was in somewhat less pain, and the stiffness of his neck was rather more marked; he was still very restless. The temperature continued about 100°. In the late afternoon he could not raise his left arm quite so readily as the right.

Saturday morning both arms were paralyzed, although he could move his fingers a very little; his breathing was entirely abdominal, and he choked when he tried to swallow. He died at 7 p.m., about two and a half days after the onset of the disease, from paralysis of the muscles of respiration. He was conscious until his death, which occurred suddenly as he was being helped from a chair to the bed.

The autopsy, on Sunday, showed no gross appearances of disturbance of the cord, but microscopic sections, made by Dr. Mallory, showed typical signs of poliomyelitis.

The points of special interest to me were the age of the patient and the fact, known to pathologists but not, I believe, to the average practitioner, that the cord lesions may not be apparent except on microscopic examination.

Milton, Mass., Aug. 26, 1916.

#### SYMPOSIUM ON FRACTURES.

##### THE IMPORTANCE OF EARLY REDUCTION OF FRACTURES WITH DISPLACEMENT.

By WILLIAM DARRACH, A.M., M.D., NEW YORK CITY.

So many bad results of fractures can be attributed to delay in reduction, and so many excellent results are obtained in fractures without displacement, that this topic seems worthy of attention. The end-results usually obtained in fractures without displacement show what may be accomplished by immediate reduction.

Let us look at the question from a pathological viewpoint. It is well, perhaps, to dissociate the lesions of the fracture itself from those of the associated injuries. By the former is meant the injury to the bone with its periosteum, endosteum and blood-vessels. Under the latter are included the coincident injuries to the adjacent structures. The relative importance of the two varies widely and may well affect our procedures. In fractures of the skull and spine, the associated injury to brain or cord, whether from displaced fragments or from subsequent hemorrhage, will far outweigh the bone lesion itself. In fractures of the pelvis the associated visceral injuries may be of prime importance.

We are dealing first with a break in the bone

and a displacement of the fragments. The periosteum is torn and stripped to a varying degree from its bony attachment. There is a rupture of blood-vessels. With the ensuing hemorrhage there may be additional stripping of periosteum. Soon, very soon, the blood coagulates and the fibrin network forms. Then follows the cellular proliferation and the organization of the clot. The early repair is like that in any wound in connective tissue, but after a few days special changes characteristic of bone repair appear, and the so-called osteoid tissue is seen. In a specimen removed at operation three days after injury the suggestion of osteoid tissue was surprisingly strong. If we turn back to what is going on in the tissues adjacent to the site of fracture we will find a varying amount of laceration of soft parts; hemorrhage advancing into the muscles, tendon sheaths, ligaments and perhaps joint cavities and along fascial planes and nerves. Following this and in a wavelike manner comes the boggy, edematous infiltration of the soft parts, the time and extent of which is clearly demonstrated by the external signs of swelling and ecchymosis. The lesser the mobility and elasticity of these tissues must impede the ease of reduction. The ideal time for reduction is immediately after the injury, and if this could be accomplished, the retraction from the bone ends would be greatly diminished. With reduction at hand, the reparative tissue formed with the fragments in their normal position will find it easier to take its proper place after reduction has been accomplished; the farther the fragments are from their normal position, the greater the difficulty.

struction; also the denser this new tissue is, the more it will interfere with the exact readjustment of the fractured surfaces. Nature begins her attempts at repair immediately and does not wait for us to reduce the displacement.

The following statements I believe to be facts:

A more exact replacement can be accomplished in the first few hours than if the reduction be delayed, especially if that delay be a matter of days.

The percentage of perfect anatomical results will be much higher with early reduction.

The ease of reduction to a large extent will vary inversely with the time elapsed since the injury.

The additional trauma caused by manipulations during reduction will be reduced.

The evil effects of pressure of a displaced fragment on adjacent structures will depend on the duration, as well as the amount of that pressure.

With a more perfect reduction comes a decrease in the amount of new tissue necessary to repair the injury, which means a lessening of the period of disability and a more complete return of function.

Lastly, the amount of pain and discomfort subsequent to the reduction will be lessened.

Shall we wait for an x-ray? It must be accepted that with a proper x-ray examination (and that includes always views in two planes, better stereoscopic and best of all with the aid of the fluoroscope) a more perfect reduction can be accomplished with less additional trauma than if it is done blindly. Whenever such an examination can be made within an hour or so of the injury, I believe we should wait for it. But if we must delay over night, or over Sunday, it is wiser to proceed without the aid of such examination. The differences between the two-hour reductions and the twelve-hour reductions are not very great, but after forty-eight hours the difference is marked, and to be able to make a second attempt within the plausible time is a strong reason for the immediate attempt. My preceding remarks apply to the closed reduction of fractures and not to the open method. The problem in open reductions differs in two respects; first, we are able at operation to remove the tissue interposed between the fragments in the early days of repair, and so to obtain a more exact replacement; and, second, a new factor is introduced, namely, infection. To combat better the latter we should wait for a few days until the body has had a chance to recover from the stunning of the original injury, before we add a second trauma; until the army of defense has had a chance to mobilize, and the war zone has been properly entrenched against the invading bacterial hosts. But this delay should not be overlong, as those of you who are doing open work well know the difficulty of obtaining and maintaining reposition where the dentations have been filled with

tissue hard enough to need the chisel, or where sharp margins have been rounded off so as to blur the landmarks. In this same connection many cases now requiring open reduction would never come to the operating table had proper attempts been made on the day of injury.

To quote from a former paper, "That odious dictum, 'wait till the swelling goes down,' is responsible for more permanent deformities and lasting disabilities than its author should care to contemplate."

Therefore, gentlemen, if there be any truth in what I have said, may I draw the following conclusions?

That our hospitals should be so equipped that the x-ray plant is available at any hour of the day or night, including Sundays and holidays.

That fractures should be considered in the same emergency class with ruptured ulcer and acute appendicitis.

---

### THE TREATMENT OF HIP FRACTURES.

By F. J. COTTON, M.D., F.A.C.S., BOSTON.

THE best way to be sure of satisfactory results in hip fractures is to have a system and a conviction; that makes it unnecessary to look up results.

A year ago a surgeon of deserved international reputation told me that if I would only use the Maxwell method always, I should never have any trouble with hip fractures; he never did. And he believed it!

The fact is the results are wretched. The unavoidable mortality is not small; the proportion of permanent cripples (total or partial), judging by data from Scudder and others, as well as my own, will run over 50% in any hospital series, and the private cases not much better.

When one comes to study cases and results in any number, it is obvious that there are two classes,—the trochanteric and the subcapital (probably better terms than the older extra- and intra-capsular). The two classes divide sharply; in the trochanteric it is a question of position only; in the subcapital, we have not only position to consider, but a very real question—whether bony union or really close fibrous union is going to occur at all. This is due partly to the poor nutrition of the separated head; partly to the interfering presence of synovial fluid.

And the risk of non-union is not only in fractures loose from the time of injury, but also in those apparently impacted, as shall presently be shown.

Now as to the trochanteric cases. First as to types (Fig. 1). Now there is no question about union in these cases; they unite by massive callus—usually promptly. The

FIG. 1. Types of extracapsular hip fracture. Nearly three-fourths of the cases of this type A, and nearly all the cases of this type B. The lesser trochanter split off as a separate fragment. Note the coxa vara deformity in both A and B.

question is purely one of deformity. There is apt to be outward rotation, easily taken care of, but the real deformity is a coxa vara type; an increase in the angle of the neck with the shaft (Fig. 2). With this goes a ten-

Now, everyone has been claiming everything for his pet method in *all* hip fractures.

I have tried to attack the problem of failure of bony union in subcapital fractures. I am going to try to give an idea of the reality of

FIG. 2. Extracapsular fracture, obli. united. C, coxa vara deformity.

dency to adduction contracture, muscle shortening, common to all hip injuries. Any treatment that ensures a reasonable amount of abduction is adequate for this class.

The Maxwell method works; the Whitman method works; and of late I have been trying Moore's scheme of a double spica in flexion and abduction, in which patients can be sat up erect,—a method of advantage in feebler patients, and of real comfort. This works, and I understand Binnie's method of sitting them up without apparatus gives good results, though I have not used it. One doesn't need *forced* abduction; simply the prevention of adduction deformity, that's all. (Fig. 3.)

The subcapital breaks, on the other hand, are essentially intracapsular, and therefore have no massive callus. Some are impacted in the beginning, and if they stay impacted, they unite by bone, slowly. If they start loose, or work loose, they do not unite by bone, and produce cripples,

this problem; of the frequency of failure along conventional lines; then to speak of my attempts.

There are, of course, some cases in which there never was any impaction (Fig. 3, B).

others, not impacted, but still, in my opinion, not adequately impacted. These cases, I believe, all require external fixation, and I have seen rare failures of bony union in these cases.

FIG. 5. A, Fresh neck fracture—hardly more than a crack.  
B, Same, forty-four days later. Note absorption of length of femoral neck without loosening of bony contact.

FIG. 6. A, Accidental impaction. This loosened without fresh accident.  
B, Pull; C, Push, taken five months later, showing what happened in the end. A wretched clinical result.

5). During this stage, or later, many a hip falls apart (Fig. 6).

My idea was to secure to the loose fractures the advantage of impaction; to re-impact those that needed correction; to fix them all in a

FIG. 7. Two end-results of artificial impaction.

B was taken at 15 months.  
Both these patients walk without a limp. Both were shown in October before the Clinical Congress.

moderate abduction. This I have done for some six years, in about thirty cases.

The method has been of hammer impaction (after reduction) and a plaster spica. No harm has resulted in any case. The plates show some of the results (Figs. 7, 8, 9, 10.).

FIG. 10. Loose fracture. Mallet impaction. Figure to the right shows condition six weeks later. Is now beginning to walk.

It is my contention that these results are encouraging; that no one has shown better results in intracapsular cases.

The other cases do not strike me as worth quarreling about; they do well under any careful treatment. The question is: Is this the best way to treat this class; the unimpacted or poorly impacted subcapital fractures; the ones that have in the past given such lamentable results, even in competent hands?

FIG. 8. Artificial impaction. A, Before; B, After; C, Three months later. At six months has not over five-eighths inch shortening and promises an excellent result.

B, Shows result two weeks later. (From x-ray through plaster spica.)  
C, Taken four months later.

# CERTAIN FACTS CONCERNING THE OPERATIVE TREATMENT OF FRACTURE OF THE PATELLA.

BY CHARLES L. SCUDDER, M.D., BOSTON,  
AND  
RICHARD H. MILLER, M.D., BOSTON.

THE method followed in the operative treatment of fractures of the patella at the Massachusetts General Hospital by the staff as a whole has been essentially uniform. This operative method has consisted in approaching the joint through an ample incision, removing gently all easily obtainable blood clot, freshening the bony surfaces of the fracture, approximating the fragments by manual pressure, suturing the capsule and torn fascia with chromic catgut, closing the skin wound, immobilizing the knee for a few weeks, allowing the patient to walk with the knee still immobilized, and in using active motion and massage early after operation. It occurred to us to study these cases of fracture of the patella thus treated by operation in order to determine, if possible, whether the method of treatment, so generally used in the clinic, is really satisfactory. If the method is not satisfactory, to determine in what particulars it is unsatisfactory, and how the treatment can be improved.

This paper is based upon the studies of a series of consecutive and unselected cases from this same clinic, which were very carefully examined, and x-rays of each case were taken by Dr. Walter Dodd and Dr. George Holmes.

Fractures of the patella treated by non-operative methods ordinarily result in ligamentous union. Ligamentous union occurs because of an absence of bony contact of the fragments. The securing of bony contact, or complete reduction of the fracture of the patella, is usually impossible by non-operative methods, because the lacerated fascia and soft parts drop between the fragments as curtains of interposing soft tissue. Moreover, by the non-operative treatment the bony fragments cannot be approximated satisfactorily if there is extensive tearing of the lateral fascia and capsule of the knee joint, which very frequently occurs.

In the operative treatment of fractures of the patella, it is desirable to avoid non-absorbable suture material whenever possible. The end to be sought in fracture of the patella is a perfect anatomical result, despite the fact that certain cases with ligamentous union have had functionally useful knees.

In this series there are two facts which stand out prominently. First, 81% of the cases have demonstrated bony union of the patella following the use of the absorbable suture combined with digital and suture approximation. This means that there is 19% of failures in securing bony union. The fracture is not reduced in 19% of the cases.

Letters were written to all cases of fracture of the patella operated upon during the

past few years. Combining those patients who reported in person and were examined, with those who simply answered letters, there were 38 cases in all. Full extension in motion at the knee joint was reported in 94% of the cases, full flexion in 60.5%, and full extension and flexion in 57% ; 63% of the cases reported that they were able to work as well as before the injury.

Twenty-two cases were x-rayed, showing the condition of the patella following operation at the end of one year or more. Complete bony union existed in 81%. Of these, 18% had union only by a bridge of bone; 18% had absolutely no bony union. All of these cases, save one in which wire was used, were sutured with silk, catgut or kangaroo tendon. In the case sutured with wire, the wire broke and there was no bony union. Surprisingly good functional results were found in the cases with no bony union.

It is evident that digital approximation of fragments and suture of the soft parts does not bring the bony fragments accurately into apposition in all cases and does not maintain such apposition. Bony apposition can be secured, we believe, by using some method of accurately approximating the patellar fragments. This can be accomplished by the clamp devised by one of us (C. L. S.), and which will be reported later in detail. It is not proposed to use this clamp in all cases, but only in such cases as cannot be reduced accurately without it. It is a means to an end in a few patellar fractures, and, of course, can be utilized in old, ununited fractures with great separation of fragments.

In this series of cases it was apparent that the functional disability most evident is the very considerable limitation of flexion of the knee; 39.5% of the cases had less than full flexion. How can we increase the number of cases having full flexion?

There are evidently several factors influencing the restoration of the joint to normal motion. One of the important factors, and the one we are particularly concerned with at this moment, is the preservation of the anatomical patellar surfaces. If the bony surfaces of the patella are restored to normal, then one of the causes of the functional disability will have been removed.

From this study of the series of cases occurring in this hospital, clinic we have come to the conclusion that in order to secure the results of the operative treatment of patellar fractures we must try to secure bony union. Bony union through the use of the absorbable suture combined with digital and suture approximation of the fragments of the bone is not always obtainable. We must use a clamp to accurately approximate the fragments, and we must use a suture which will maintain the position of the fragments. Wire or kangaroo tendon is not a suture which will maintain the position of the fragments in all cases as well as the absorbable suture.

the fragments, the patellar clamp may be employed with gratifying results.

After the reading of this paper, Dr. Miller demonstrated by lantern slides certain of the facts brought out in the paper, giving the details of the cases referred to in the lantern slides.

#### SOME ASPECTS OF THE TREATMENT OF COMPOUND FRACTURES UNDER CIVIL AND MILITARY CONDITIONS.

By DAVID CHEEVER, M.D., BOSTON.

ONE must be an optimist indeed who hopes and believes that out of the brutal chaos of the present war may come some good to suffering humanity; yet we doctors may dare to indulge in optimism, for surely, from the unprecedented experience and mass of data now being accumulated by the surgeons of the warring nations, progress is certain to be made in the control and prevention of disease. Sanitation, the extermination of flies, lice, mosquitoes and other intermediate hosts of infection, the prophylaxis of epidemic disease by vaccination or inoculation, the study of the control of infection in wounds, the healing of wounds, advances in the knowledge of the physiology of various organs, especially the central nervous, the cardio-respiratory and the digestive systems, gained by opportunities for observation offered by the traumas of warfare, are examples of fields where progress is already recorded. Among the special problems, few are more pressing than those presented by compound fractures, the treatment of which in warfare is sadly lacking in authoritative standardization, though doubtless in civil practice much more uniformity exists.

Simple fractures (excluding fractures of the skull) present chiefly the largely mechanical problem of the promotion of repair of various parts of the skeleton, and to a less extent the combating of shock or the conditions which may attend the enforced invalidism of the patient; compound fractures present the possibility of a much greater degree of shock (perhaps associated with hemorrhage) and the problem of wound infection. This latter condition, with its attendant possibility of death, must take precedence in its demands over all other considerations of treatment, for methods, however skilful in fixation and immobilization, which do not yield precedence to the proper primary and subsequent treatment of the wound, are almost sure to result in disaster. Fortunately, in most instances, the two objects are not incompatible, though some afford the most perplexing and baffling difficulties with which surgeons have to deal.

Only those whose experience or recollections

go back to the pre-Listerian days can have any graphic conception of the miracle wrought by antiseptics. Then such an injury meant the serious consideration of amputation as a primary measure, or resort to it, sometimes too tardily, during the course of the case; now the expectation is justified that a compound fracture will do well. In civil practice, such an injury presents usually but trivial difficulties, compared with those under conditions of warfare. Commminution of the bone is absent or moderate in degree; the wound is apt to be small and the soft tissues not devitalized by trauma; the infection from skin, clothing or soil may be of a slightly virulent type; prompt treatment and disinfecting measures are applied before the infecting organisms have time to multiply; the prompt arrival of aid (in civilized communities) minimizes shock from hemorrhage, pain, exposure and hunger, and the problems of transportation are usually not significant. The treatment of these conditions (except as relates to wound disinfection) is so generally standardized that but few suggestions may be offered. First, in cases presenting a comparatively small wound, where the bone-end, after perforating the skin, has retreated to its normal bed, it is usually wiser not to enlarge, explore, and disinfect the wound, but to assume that serious infection has not taken place, and keep careful watch for its appearance. My own practice is to seal temporarily the wound with sterile gauze, while the surrounding field is cleaned with soap, water, alcohol and some disinfectant solution, touch the edges of the wound with iodine, insert a very shallow gutta-percha-tissue drain, and apply a wet antiseptic dressing of hypochlorous acid or bichloride of mercury (the biniodide may be better since it is said not to coagulate albuminous fluids). If infection is present. Nature, here, as elsewhere, will probably succeed in localizing it under the favorable conditions surrounding our patient, and close observation will give ample warning for interference to be effective. I feel certain that the routine exploration of these small wounds and the applying of gross efforts at disinfection with swabs and scrubbing brushes, do more harm than good. The second suggestion that I offer is that means of internal fixation, especially bone-plates, are by no means contraindicated by the infection of wounds of compound fractures. In such lesions of bones near the surface, such as the tibia, ulna, radius, humerus and clavicle, where satisfactory position cannot be obtained by external splints, which afford free access to the wound for purposes of dressing, bone plates may be applied as temporary internal splints, intended to be removed when union in good position is assured, usually three or four weeks. The external splinting and dressing of the wound is thus enormously simplified. The wound should be packed open by gauze within gutta-percha tis-

sue, and dressed, when necessary, with scrupulous care. In spite of the packing, the tissues sometimes will heal completely over the plate. No anesthetic (save possibly a little novocaine infiltration) is required for its removal. The writer has thus plated, without untoward results, the tibia, ulna, radius and clavicle. The humerus should usually be susceptible to the same treatment. The deep position of the femur may contraindicate it.

The compound fractures caused by the projectiles of the present war present special features, the most important of which may be enumerated. The comminution of the bone may be extreme, so that several inches of the shaft are reduced to splinters. The high velocity rifle bullet at close range imparts its own terrific momentum to the bone fragments and scatters them; this effect is enhanced by the explosive action of the zone of compressed air preceding the bullet. At longer ranges, when its velocity is less, its flight more steady, and the oscillation of its base has ceased, it may make a clean perforating hole through bone. The writer has thus seen the clavicle cleanly perforated without fracture, by a German rifle bullet. But, again, towards the end of its flight it becomes more destructive, the heavier base tends to overtake the point, and the bullet somersaults on striking, inflicting serious wounds of soft tissues and bones. Shell fragments, according to their size, produce much comminution, and the round lead shrapnel balls produce either a comminution of the shaft without much displacement, or bury themselves in the cancellous tissue of the ends of the larger bones. The soft tissues are frightfully confused by the explosive effect of the high velocity projectile or the ragged shell fragment; the tissues are seriously devitalized over a wide area, and extensive intermuscular planes opened up, conditions most favorable to the multiplication of bacteria. And bacterial infection is almost certain to occur. The soil in the Western theatre of war, highly fertilized for generations by human and animal excreta, is teeming with bacteria, especially the spore-bearing anaerobes. The soldiers, living the life of moles, burrowing in earth and mud, are plastered with this infected soil. Consequently, every projectile piercing the foul clothing and dirty integument carries with it pathogenic organisms into the wound, and especially the shell fragments, rough and irregular in shape, are apt to punch out and push before them a wad of the various layers of clothing. Fleming,<sup>1</sup> working under Wright's direction, made cultures from twelve average samples of soldier's clothing fresh from the trenches, and found in 10 cases contamination with the bacillus of gas gangrene (*B. aerogenes capsulatus*); in five cases, streptococci, in four cases, the tetanus bacillus; and in two, staphylococci. In other words, we may conclude that a large majority of all cases are potentially infected with gas gangrene. Inci-

dentally, it is striking to reflect on the efficacy of the prophylactic injection of tetanus antitoxin, in view of the widespread contamination of clothing with *B. tetani*, apparently revealed by the above figures. In three months' service in Northern France during the past winter, the writer did not encounter or hear of any case of developed tetanus. Undoubtedly, the best hope for the future in the treatment of gas gangrene and infection by pyogenic organisms lies in the development of antitoxins and vaccines of equal reliability with that of tetanus. To the above enumeration of the unfavorable conditions attending these compound fractures, must be added the profound shock and exhaustion due to prolonged exposure to cold, wet, hunger, nervous strain, the frequently co-existing hemorrhage, and the length of time that may elapse before aid reaches the wounded man. Soldiers hit in the open cannot be picked up until darkness comes to give some protection to relief parties, and even in the trenches it may not be possible to convey them back to the field ambulance until nightfall. The totally inadequate first-aid dressing thus may be the only treatment, which may at best prevent further contamination, but cannot hope to affect the infection already introduced.

In the face of this almost inevitable and virulent infection, the first consideration must be its adequate treatment, and perfect mechanical immobilization of the fragments is at first of secondary importance. As Bowdly<sup>2</sup> points out, this aspect of compound fractures varies with the geographical situation of the battlefield. In the South African War, the virgin soil uncontaminated by manure, and the hot dry climate were strong factors in lessening the incidence of infection, factors aided by the fact that the blunt-nosed bullets of lower velocity of that period had much less traumatizing and divulsive effects on the tissues; and shell wounds, and consequently the carrying in of extraneous material, were much less common.

Granted, then, under the conditions at present existing in Europe, a compound fracture caused by a projectile, the rule is that proper drainage and disinfection must be carried out at the earliest possible moment. The only exception to this rule is the case where a high velocity rifle or machine gun bullet at medium range has passed through a limb, breaking the bone but without showing the explosive effects described at other ranges. In such a case there may be minute perforating wound of entrance and exit already sealed up, without contamination. The sharp-nosed bullet, on the other hand, has clothes and skin and soft tissue around it devitalized. Interference with the wound, to replace the lost tissue, is a serious matter. It may be left alone and sealed up, but it is almost successful only if the steps in the preceding writer's observations are followed.

At a point in the foregoing observations, the

ity of cases, an anesthetic must be given, the wound of entrance and exit thoroughly opened up, all contused, devitalized masses of muscle, fascia or fat radically excised, since it is in them that the bacillus of gas gangrene will most surely find a favorable nidus, and every nook and recess of the wound explored. Early interference is essential, for Carrel's<sup>3</sup> studies have shown the comparative scarcity of organisms in the recent wound, and the unbelievable rapidity with which they multiply. From this point forward there is scarcely a step recommended by some whose utility is not denied by others. Shall comminuted fragments of bone be removed? Obviously not, if large and well attached by periosteum or muscle. Some authorities urge the immediate removal of all small fragments, whether attached or not; others practise it only in the case of wholly free fragments; others, among them Robert Jones,<sup>4</sup> say that loose fragments may be taken out, cleaned and replaced, and may be expected to unite. The writer must confess that in wounds so universally and virulently infected, such a miracle seems hard to believe. In his own brief experience, fragments of doubtful viability invariably had to be removed, and before removal interfered with proper drainage, and seemed to prolong infection.

How shall the wound infection be combated? Everyone who treats infected wounds shares the disappointment experienced by the profession at large, when Lister's discovery failed to produce a means of destroying organisms in the tissues as well as in the test-tube. Skepticism as to the efficacy of antiseptic solutions in cleansing wounds has enrolled many surgeons among the followers of Sir Almroth Wright,<sup>5</sup> who has sought to encourage and utilize the resisting agencies of the patient's own body fluids by the use of hypertonic saline solutions for irrigation or gauze packing of wounds. A copious outflow of lymph is provoked, which may be supposed to wash out the organisms which have already entered the tissues beyond the reach of antiseptic solutions, and inhibits their multiplication by the antibodies it contains. Moreover, the 5% saline solution is said to be actively bactericidal. When for the hypertonic solution is substituted a normal saline solution, leucocytes are attracted in greater numbers, and by their phagocytic action tend especially to clean up streptococcus infections. While many wounds under the writer's charge, after proper drainage had been instituted, did well under the hypertonic treatment, the very striking results reported by the originator were not often duplicated. The writer, like others, is compelled to acknowledge the comparative inefficiency of antiseptics in badly infected compound fractures, but he does not share the belief that such solutions act beneficially solely by the mechanical washing away of organisms. When used early before the organisms have penetrated the tis-

sues, they are of great effectiveness; when used later, they still destroy any free organisms, are on hand to attack others as they are thrown off from the tissues, and are useful in preventing infection from patient to patient. Granted that there can be found an antiseptic practically innocuous to the tissues and yet possessed of bactericidal powers, it would seem that its free use in infected compound fractures was the most rational treatment. Such an antiseptic seems to have been rediscovered in hypochlorous acid or its salt, hypochlorite of sodium. It is strongly bactericidal, apparently quite harmless to tissues, cheap, easily produced. In the writer's experience, badly infected compound fractures may be most effectively cleaned up, after incision, removal of all devitalized tissue, and establishment of proper drainage, by the free use of hypochlorite solution as constant irrigation or as wet gauze packing, frequently saturated and kept moist. Its harmlessness is shown by the employment in a number of instances of a solution of hypochlorous acid as an intravenous injection in septicemia, with good results.<sup>6</sup>

The number of splints devised to immobilize compound fractures is legion, and testifies eloquently to the imperfect character of the majority. In the writer's opinion, plaster of Paris, even when used in the most skilful manner, is inappropriate for these cases during the stage of their acute infection. Its dressings are heavy, cumbersome, take much time for their application, often do not provide effectively for extension, and, worst of all, it is almost impossible to keep them from contamination with wound discharges or irrigation fluids. In the secondary treatment of these cases, when bone grafting or other corrective measures must be tried, plaster finds its field of usefulness. The most universally useful type of apparatus is the Thomas knee splint, or one of its numerous modifications, such as the Page splint, in which the ring for counter-pressure is replaced by a curved piece, forming three-fifths of a circle. These splints are simple, cheap, easily made, and durable, and adapted for almost all fractures of either lower or upper extremity. Extension is secured by surgeon's plaster extension straps, applied in the usual way, which are then secured to the transverse bar at the distal end of the splint, forming a fixed extension. The limb is prevented from sagging by slings or gutters of perforated zinc or aluminum, which are adjusted to suit the individual case and interrupted, if possible, opposite the wound; or, if the latter is too extensive, these perforated strips of metal are sterilized by boiling, and applied directly beneath the wound, whose discharges pass through the perforations into the dressing. These splints allow of easy transportation, and when suspended to the horizontal bar of a Balkan splint, or better still, to one of the many ingenious travellers on a modified Balkan splint, they permit of the patient moving quite freely

about in bed without disturbing either the alignment or extension of the limbs. Certain fractures of the femur present special problems, which have been met, in the case of fractures of the upper third, by Jones' abduction frame, and in the case of very extensive multiple wounds, by the ingenious suspension hammock beds of Sinclair<sup>7</sup> and others.

It is interesting to find that the use of bone plates as temporary splints in infected compound fractures in civil practice, as just recommended, has been duplicated and strongly urged by some observers under the conditions existing on the battlefields of France. Lake<sup>8</sup> advises the plating of infected compound comminuted fractures of long bones, thus securing the maintenance of proper length, making external splinting unnecessary, and making the dressing of wounds and treatment of sepsis infinitely easier. During the first three or four days after the receipt of an injury, he makes vigorous efforts to diminish the sepsis, then the plate is applied and left for three to four weeks. He reports no ill results from infection of healthy marrow and finds that the screws do not loosen so prematurely as to impair the results. Pennell<sup>10</sup> is even more radical, advising this procedure as a routine, and claiming that he has rarely had to remove a plate. The writer confesses that the degree and virulence of the infection and the extent of the trauma seemed to preclude this method in the cases under his observation, but in view of the good results reported, he believes that the method deserves a fair trial.

## DISCUSSION.

DR. ROBERT W. LOVETT, Boston: The part of the subject that I wanted to speak of in this discussion is the question of fracture of the neck of the femur and the difficulty of getting it to unite, because, of course, this is a difficulty that

we all are constantly meeting. The orthopedic surgeon, perhaps, sees the worst cases, because they are apt to come at the end, when everything else has failed, and in these cases he is naturally at a loss to know what to do, so that anything that can be done to diminish the number of these cases of non-union is most desirable.

One difficulty comes in the interpretation of the early x-rays, because in the x-ray we are apt to forget that we are looking upon the contour of two irregular surfaces, and it is very easy for the two shadows to overlap each other in such a way that there appears to be union. Many of these cases, however, when they begin to walk show by the stretching of the apparent union that there never could have been good union there, and I have seen many cases in which in the early stage the opinion was expressed on the strength of the x-ray that good union had occurred, yet where stretching began when walking was undertaken.

The experience in coxa vara which we have at the Children's Hospital bears somewhat on this question. Coxa vara, as you know, is a depression of the neck of the femur to a right angle with the shaft, and the routine treatment that we use in these cases is forcible abduction of the leg under anesthesia, with a view of inducing a fracture of the neck of the femur. In other cases we divide them with an osteotome in case they are resistant to the simpler method. Under these conditions we have an artificial fracture of the neck of the femur—slides shown here.

In a series of these cases it has been very definitely shown that we get a better position of the fragments if we add traction to abduction. With simple abduction the fragments tend to slip by each other, but with abduction and traction, as shown in the slides, we get excellent apposition.

It is not unlikely that this may have a bearing on the treatment of the fracture of the neck of the femur, where, instead of using simple abduction, we should probably get better position if we added traction to the abducted position.

DR. J. B. BLAKE, Boston: I have seen a case in which it is not possible to follow the suggestion of Dr. Lovett, and that is a compound fracture of the neck of the femur. Dr. Scudder and Dr. M. J. Keen have been very successful in treating it by the use of the interpedal hammock bed. I was told that the patient was able to walk in a few days after the operation.

THE PRESIDENT: I am sure that the use of the interpedal hammock bed is a very valuable method of treating compound fractures of the neck of the femur. It is a method that is well worth trying in such cases.

importance, with the laceration, more or less complete, of a very wide tendon, and finally with an injury which invades the largest joint in the body. Therefore, unless we are careful, we may make an illogical deduction and may inaugurate treatment as if the injury was a simple fracture and nothing more. We must remember that it is not simply the apposition of the fragments of a broken patella that is essential to good and complete motion later, but the accurate and complete suture of a great tendon and its lateral expansion. Indeed, it is quite possible that the result, so far as the patient is concerned, may be admirable, and yet there may be a distinct separation of the patellar fragments. It would probably be best to teach the students the treatment of fracture of the patella on the basis that it is not primarily a fracture at all, but that it is a tendon wound which must be repaired. Furthermore, this tendon adjoins a great joint cavity, and once infected the sepsis is horrible, meaning often a loss of the patient's life, or invariably a damaged or annihilated joint. This danger of sepsis is by no means theoretical. It has occurred in the hands of most skilful surgeons and under all possible hospital precautions. It is obvious that only those who are properly trained should undertake such operative measures.

Not all cases of broken patella should be operated, and the reason is that some are only fissured or comminuted fractures without displacement, that is, without laceration of the quadriceps extensor. In these cases fractures of the patella unite well because the fragments are held close together, and since there is no laceration of the tendon, there is nothing to repair. These are what Dr. Joseph Blake spoke of as direct violence fractures, which form a small percentage of the total number. The tear fractures are due to indirect violence. There are, of course, varying degrees of separation in the indirect fractures according as the tear is more or less complete. This, on careful examination, will be found to vary widely. I have seen tear limited almost entirely to one side of the patella. Surgeons will vary in judgment of the amount of separation of the patellar fragments which indicate operation. I should differ with Dr. Scudder on this point, since I should operate in any case in which the separation of the patellar fragments was equal to a finger breadth, assuming that there were no other contra-indications to operation.

All compound or open fractures are to be operated as a matter of course. As a rule, five to eight days should intervene between the accident and operation; this gives an opportunity for the establishment of constitutional immunity. The general contra-indications to operation are extreme age, poor general condition, and threatening delirium tremens; of these, the most important is threatening delirium tremens. In some sixty cases, I have had one death. This

was due to delirium tremens, and not to the fact of the particular operation. The operative result was excellent; a first intention wound and normal temperature for ten days, then acute delirium tremens set in and the patient died of terminal pneumonia. The mistake in this case was not the fact that I operated upon a fractured patella, but that I did any surgical operation whatsoever.

The technic demands absorbable sutures, and only absorbable sutures, except in the rare cases in which wire is absolutely necessary to maintain apposition of patellar fragments; when the torn ligaments have been approximated, the patellar fragments will come together closely, since the clot and the interposed ligament and periosteum have been removed.

I think Dr. Scudder's clamp will be of distinct advantage in a certain number of cases. Screws and plates, however, are never indicated in my judgment. The danger of using wire is very well shown in one of Dr. Miller's x-ray plates, where the wire was broken and apparently entered the joint cavity.

As to refracture: Refracture may be expected to occur wherever secondary violence is equal to and is applied in a manner similar to that which caused the original fracture. I have had one case in which the patella was fractured four times.

DR. JOHN HOMANS, Boston: My discussion will have to be confined to the treatment of fracture of the neck of the femur. I should like to have spoken on Dr. Darrach's paper, the subject of which seems to me very important, but I was too late to hear it.

I had the honor of helping Dr. Cotton do one of his impaction cases, and it is on that case that I am going to base what I have to say on the subject. I do not think Dr. Cotton has done justice to his own skill. It struck me in seeing him place the bones in apposition for impaction that it was a very difficult thing to do, that it required a very keen sense of touch and familiarity with joint fractures, which Dr. Cotton has; and I do not feel that most of us could replace the fracture in such accurate apposition that it will practically stay in place without being held. That seems to me something which we all of us have to acquire with a good deal of difficulty and a good many failures. Moreover, even when the bone is impacted, it seems to me that you are dealing then with a bone graft, that the head of the bone is still a pure bone graft. It has no blood supply, the blood supply having been cut off, and it has been very interesting, therefore, to follow the x-ray plates of the case which Dr. Cotton impacted at the Brigham Hospital. There was at first perfect apposition with no shortening. The head of the bone looked perfectly normal. It is now some five months, and the position has remained good. The patient has been able to use her leg, although

bearing no weight upon it, and the function is perfect, aside from the weight-bearing. On the other hand, the x-ray shows that the head of the bone is going through a period of extreme atrophy, and the last x-ray plates in this respect are different from the first ones. Whether the hip is coming out all right in the end, or whether it is coming out better than it would have under treatment by abduction only, I do not know. That may be the weak point in Dr. Cotton's treatment. If the case is not so traumatized that the repair can still take place, then he has accomplished a great deal.

If, on the other hand, the fragments could be put in apposition by any such scheme as Dr. Lovett has spoken of, I am not sure that this might not be just as good. At the present time it seems to me that Dr. Cotton has shown what no one else has, namely, that if one can place the fragments together properly, they will heal. In many cases impaction certainly does give excellent results.

I am anxious to follow our own cases with the x-ray to see how long it is before that head becomes solid and we get back the normal bone structure.

Finally, of course Dr. Cotton has spoken of the difficulty of using this treatment on the aged and infirm. It seems to me, as we all see cases in large hospitals, that we do not find a very large portion to which this treatment can be given, and the cases to which it cannot be given may very well have to be treated without any adequate fixation, and those are usually failures.

I should very much like to see a parallel series of cases treated by abduction, possibly with traction, in as skillful hands as Dr. Cotton's, having the bones placed in position but not impacted, and see that series treated alongside of Dr. Cotton's impaction cases.

DR. F. B. LUND, Boston: I think we owe a debt of gratitude to Dr. Darrach for calling attention to the fact that under temporary dressings so much swelling takes place within two or three days, that by the time permanent dressings are applied reduction is much more difficult. I have found that when I was on hand to reduce a fracture and put it up in plaster of Paris as soon as it came to the hospital, the reduction was much more easy than when it had been dressed for a few days in the time-honored pillow and side splints, and infiltration had taken place about the ends of the bone.

Another admirable point made by Dr. Darrach was that the length of time in which the pressure from deformity takes place is just as important as the amount of deformity. His paper is exceedingly sensible and timely, and should teach us that fractures are emergencies and should be treated as such.

In regard to Dr. Scudder's paper, where unabsorbable sutures are used, if there is much

tension, the apposition is not apt to remain perfect, and I think this device for holding the fragments together while the sutures are applied, and doing away with the eversion of the fragmented surface of the lower fragment will enable us to place our sutures more accurately and get better results.

Dr. Cotton seems to have come nearer getting satisfactory results in these fractures of the hip than any treatment that I have seen. In ununited cases, I have tried nailing them, with unsatisfactory results. In one case I took out the head of the femur and nailed it on to the ilium, just above the acetabulum, to act as a buttress and prevent the great trochanter from slipping by. It was not effective, and I mention it only to condemn it.

DR. W. J. MIXTER, Boston: In regard to fractures of the base of the skull, it may be interesting to say that our experience at the Massachusetts General Hospital in the past few years has approximated very closely what Dr. Harvey Cushing suggests. Between the years of 1890 and 1911, when Dr. Homans started to do the fractures, the mortality was 57%. Since that time it has been cut down to 41% and it is lower in my own cases. In the earlier series there were 260 cases, and since that time there have been 125 or 130.

I think that what Dr. Darrach said is also being said of fractures of the base of the skull. As soon as it is possible to decide whether a decompression with drainage is advisable, it should be done.

DR. J. COLLINS WARREN, Boston: I have listened with great interest to what has been said this afternoon. As I have followed the reading of the different papers it has been borne in upon me that this important department of surgery has not only come into its own again, but is being accorded the consideration which it deserves in the alignment of the new surgery. I was especially interested in Dr. Darrach's statement of the pathology of the processes which surround the repair of the fractured bone and the importance of a method of greater precision in outlining its treatment.

In old-time surgery there was a polite fiction that when the fracture was "set" and had been done that was necessary for the adhesion of the fragments. As long as they were held by in contact, even though overlapping one on another, the callus formation and the blood absorption provided for an adequate reformation of the function of the broken bone.

When, with the advent of a splint, the interior of the body became a well-defined place of interest to the surgeon, the department of surgery which we are now entering upon, of the time being to be placed in the hands of the hospital surgeon, the surgeon's attention was directed to the care of the fracture, and the surgeon's house officer, the surgeon's assistant, the

which the x-ray has brought with it has changed all this. Our knowledge of the pathology of fracture has been enormously increased, and the haphazard manipulations of the old-time surgeon have given place to methods of precision, and it is quite evident that the treatment of this surgical lesion is now being placed on a new and thoroughly up-to-date basis.

The old-time treatment of fractures, which was an opprobrium of surgery, and the source of much anxiety and misery of mind to many a practitioner will, let us hope, become a thing of the past. The standardization of this surgical lesion, which modern methods will enable us to bring about, will carry satisfaction with it to both surgeon and patient, and peradventure snatch from our brothers of the legal profession a claim upon this field of surgery, which will now become exclusively our own.

DR. WILLIAM DARRACH, New York: I quite agree with Dr. Homan on the question of hips. We must differentiate between the subcapital and the trochanteric varieties, as they are distinct. There are better results in the outer breaks and poorer results in the inner breaks.

I think Dr. Cotton's successful results are due to his good reduction rather than to his impaction.

#### THE FLEXED SPICA AND WHEEL CHAIR IN THE TREATMENT OF FRACTURE OF THE NECK OF THE FEMUR.

By G. A. MOORE, M.D., BROCKTON, MASS.

OTHER conditions being equal, poor results in the treatment of fractures are attributed either to the methods employed or to lack of skill in reduction and care during convalescence. Mobility of fragments of bone following fracture is the rule and is not considered unfavorable to repair; impactions are uncommon and are a detriment to normal repair of normal function.

The literature upon hip fractures, especially text-books, does not follow this rule regarding poor results. In this class of cases, deformities and disabilities following treatment are not attributed to the method or skill exhibited, but to the peculiarities of the anatomical structures involved in the injury, the inaccessibility of the fragments to the applications of splints, etc., the deforming influence of the muscles about the hip joint, and the lack of regeneration of bone in this region.

Mobility of fragments following injury, or the loose type of hip fracture, are the cases in which a poor prognosis is given regarding bony union, deformity and normal function following treat-

ment. In the impacted type, a more favorable prognosis is given, since a larger percentage result in bony union, though deformity and loss of function may be marked. In hip fractures the patient is considered fortunate who has an impaction of the fragments, and the rule has been generally accepted, especially in the aged, that however great the deformity, impactions should not be broken up.

The first reason for the poor results obtained in hip fractures is probably one of the chief causes in older methods of treatment, which embodied some form of traction and splints. In the complete unimpacted types, reduction of deformity and apposition of fragments is frequently accomplished, but as yet no type of splint has been devised, nor a method of application evolved by which both fragments of the neck of the femur are immobilized during treatment. One exception to this statement should be made, the Thomas hip splint or some modification of it.

In all of the methods which depend upon splints and traction for reduction and immobilization, a certain amount of movement of the hip occurs in the care of the patient's back, the use of the bed pan, changing sheets, etc. If the fragments are impacted, and the impaction does not become disengaged, these movements do not interfere with the process of union; but if the fragments are loose, movements undoubtedly retard the normal regeneration of bone.

One of the old rules, which has become an axiom in the treatment of fractures, is to immobilize the joint above and below the site of fracture. The methods advocated by Lucas-Championnière have been adopted by few surgeons, since it is generally believed that repair of bone takes place more rapidly when the broken fragments are not only accurately approximated, but are immobilized.

It would seem that the advocates of traction and splints, in the treatment of hip fractures, have accepted the teachings of Lucas-Championnière, in part at least.

Further in regard to the muscles causing deformity of fractures, it has been found that better approximation of the fragments is obtained and immobilization assured, when, if possible, the limb is placed in a position which relaxes these muscles. Traction methods disregard this principle, and depend upon reducing deformity by tiring out muscles which produce it.

In the method of abduction, as advocated by Whitman, certain principles governing the treatment of fractures in other parts of the body are maintained: (1) Deformity, if present, is reduced before the application of the plaster cast. (2) The broken ends of the fragments are placed in apposition by placing the limb in abduction and inversion. (3) The short muscles about the hip joint, which are most active in producing deformity, are relaxed. (4) The adductor group of muscles and the ligaments of

the joint, which maintain apposition of the fragments in the abducted position, are put on stretch. (5) The danger of the most common deformities which limit function—coxa vara, eversion and adductor contraction—is minimized. (6) Immobilization of the fragments is assured by the application of a cast which fixes the leg and pelvis in the position of reduction. Patients treated by the abduction method, of necessity are bed patients during treatment, but the dangers of recumbency in old patients are lessened by raising the head of the bed and turning the patient on the side.

Statistics from some of the larger hospitals are of interest as illustrating the high mortality following this injury, and the low percentage of good functional results with the older methods of treatment. Seudder, in 1907, reported the end-results of sixteen cases treated at the Massachusetts General Hospital. But two had functionally useful limbs; thirteen used crutches or cane or had disability in going up stairs. Only three of the patients, in his series of cases, were over sixty years of age at the time of injury. Walker reported one hundred and twelve cases, in 1907, treated at Bellevue Hospital, with a death rate of 16%. Eighty of these patients were traced, and but ten were found to be able to do their usual work, while ten were still in the hospital. In the same paper he reported sixteen cases treated by Whitman's method; seven of these patients were over fifty years of age. There were no deaths. Four had recovered completely and had resumed their usual work, the rest were still under treatment. In 1908, Ashhurst and Newell reported fifty-eight cases treated at the Episcopal Hospital, Philadelphia, with a mortality of 27.6%. Twenty, or 34%, they reported as cured. All of

FIG. 2.—Side view illustrating the amount of flexion necessary, enabling the patient to sit in a chair with a cast.

their deaths occurred in old patients, the ages ranging from fifty-nine to eighty-four.

It is generally conceded that fractures through the base of the neck of trochanters always result in bony union under any treatment, that disability in this class of cases is due to deformity and not to lack of union of the fragments. About 10% of all hip fractures are unimpacted at the time of injury (Colton). A certain number of these are extra capsular, and will result in bony union under any circumstances, reducing the number of loose intra capsular fractures below 10%. From 15 to 27% of all cases treated by the older methods die, which will further reduce the percentage. Probably there are about 6 or 7% of all treated hip fractures which are of the unimpacted intra capsular variety at the time of injury. The number of cases of disability following hip fracture, resulting from deformity alone, is few compared with those whose disability is due to lack of union. Since it is the unimpacted intra capsular variety of fractures that results in imperfect union, it is to be inferred that a large percentage of the poor results, following the older methods of treatment, is due to impacted fractures becoming loose while undergoing treatment. While absorption of the ends of the fragments, lack of penetration of bone and poor blood-supply are factors, the main one at the hip, permitted by traction and special methods of treatment, is probably the greatest factor in the cause of this catastrophe.

In most of the methods of treatment of hip fractures, which have been advocated in the past, recumbency of the patient is a requisite for their application. In attempting to maintain reduction of the fracture, it has been considered as a matter of course that the patient is really

FIG. 1.—Front view of cast, taken about eight weeks after injury. There is some eversion of the foot, after correction of eversion.

as possible the same horizontal plane as the body. To maintain this relationship between the position of the injured leg and body, the Bradford frame and Liston side splint are used in traction methods, and in Whitman's abduction method the cast is applied well up on the chest.

The most frequent causes of death following this injury in the aged are shock, hypostatic pneumonia, exhaustion and decubitus. Of these,

become wheel-chair invalids with a loose fracture for the remainder of their days.

About four years ago, August, 1912, while treating one of this type of cases, a man of seventy-eight, for whom recumbency seemed inadvisable, the idea suggested itself that a plaster cast might be applied upon the same general principles embodied in the Whitman method, modified to permit the patient to sit in a wheel chair. The fracture was the loose extracapsular

FIG. 3.—X-ray of left hip, before treatment. Same patient as in Figs. 1 and 2. One inch shortening, moderate eversion.

hypostatic pneumonia probably claims more unfortunates than any of the other complications. To guard against this, in the Whitman method, the head of the bed is kept raised and the patient is frequently rolled upon the side. In traction methods, such preventive measures are impossible owing to the extension on the leg and the splints. At the onset of serious complications, treatment of the fracture is immediately discontinued, apparatus removed if necessary, and the patient placed in a sitting posture. In many old, feeble patients, this is the only method that will save life. As a result, they

type, base of the neck or through the trochanter. No x-ray was obtainable. There were  $1\frac{1}{2}$  inches shortening. As there seemed to be no contraindication to applying the cast under anesthesia an anesthetic was administered, the patient placed upon a spica board, the leg drawn down to reduce shortening. Then the thigh was flexed to nearly right angles with the body, abducted as far as possible and inverted. The knee was flexed at right angles with the thigh, and in this position the leg was lifted upward strongly. An assistant then held the leg in this position while a cast was applied from just

above the costal margin to about half-way down on the calf of the leg. The cast was strongly reinforced in the groin, and in the back the reinforcing was carried far inward over the ischium. On the uninjured hip it was brought well down over the trochanter. The patient was then put on a high head rest in bed. The following morning he was assisted into a wheel chair, and each day thereafter during the five weeks he remained in the hospital. He was then

sixteen patients have been treated by the flexion method. In reporting this series of cases, one other should be included, whose condition did not warrant any treatment. This patient had pneumonia when first seen, and died about three days later. There was one other death in the series. A cast was applied at home. As a result of incontinence, it became necessary to apply a second cast. The patient was attended by her family physician, and I did not see her

FIG. 4.—Same patient, leg in abduction, with cast on foot.

sent home to be attended by his family physician. This patient had a rather troublesome incontinence of urine, which necessitated applying a new cast at the end of three weeks. There was also considerable swelling of the foot and leg below the cast, which was relieved by a firm bandage. Otherwise his convalescence was uneventful, the cast was removed at the end of ten weeks, and at the end of four months he had normal use of the leg.

The results, in this case, were so gratifying that it was decided to apply this method of treatment in other cases. Up to the present,

for several weeks. I learned that, through the nurse's neglect, decubitus developed, resulting in septicemia and death. Now of the sixteen patients were over seventy, and of the twenty of the hospital, is eighty-seven. There were between sixty and seventy three between fifty and sixty, and between forty and fifty. Seven patients had been treated previously and were able to bear the treatment. In two the result has been good, but in these was the loss of the foot. In the remaining cases, the result has been good, with the exception of one case, in which the foot was lost. In the remaining cases, the result has been good, with the exception of one case, in which the foot was lost.

and no other visible deformity. The disability is apparently due to weakness of muscles. Three patients are still under treatment. Two have not been traced and one died of grippe twelve weeks after injury, after his cast had been removed and he was walking on crutches.

It has been found that patients are much more comfortable when the cast is applied the entire length of the leg, covering the foot, and

FIG. 5. Cast removed.

the method of applying the cast down to the calf of the leg has been abandoned.

In two of these patients, a double spica was applied, but both were so uncomfortable that it became necessary to remove the cast from the uninjured leg. If the cast is applied so that it embraces the great trochanter of the uninjured leg, the single spica immobilizes the pelvis as completely as the double spica.

In the dissected subject a comparison of the Whitman method and the flexion method is of interest with regard to the muscles which aid in maintaining reduction:

Ligaments of capsule: Tense.

POSTERIOR DISSECTION.

Gluteus maximus: Relaxed.

Gluteus medius: Relaxed.

All short muscles about hip joint: Relaxed.

Ligaments of capsule: Tense, except ilio femoral.

POSTERIOR DISSECTION.

Gluteus maximus: Tense.

Gluteus medius: Very tense.

Other short muscles about hip joint: Relaxed.

#### SUMMARY.

There is a relaxation of the adductor longus and the ilio femoral ligament of the capsule in

the flexed position that does not occur in extension with abduction. In flexion the gluteus maximus and medius are very tense, acting as a support to the trochanter, preventing backward displacement of trochanter and eversion.

Regarding the position of the trochanter in extreme abduction: about fifteen dissected subjects were examined at the Harvard Medical School, through the kindness of Dr. John Warren, and while in some the trochanter could be placed within about one-half inch of the side of the ilium, in none could it be made to impinge on the ilium.

#### CONCLUSIONS.

The flexed spica is a modification of Whitman's method of treatment of hip fractures. Reduction of deformity and apposition of the fragments is maintained by essentially the same means. The chief difference is that, instead of the abducted and extended position of the leg, it is immobilized in the abducted and flexed position, permitting the patient to assume the sitting posture. Results have shown that maintenance of the leg and body in the same horizontal plane are not essential to union or good functional results. This method was devised for old, feeble patients, who are able to tolerate some appliance for immobilization, but in whom methods necessitating recumbency seem inadvisable. The results following its use have been much better than were hoped for.

Seventeen patients have been treated; fifteen were over fifty and nine of these were over seventy years. So that, in this series of cases, the method has been applied in the class of cases for which it was devised. There were but two deaths,—one a hopeless case when first seen, the other, through neglect of the nurse, developed decubitus, resulting fatally.

The last patient treated was a woman of eighty-seven, who is about in a wheel chair every day without discomfort.

There was one case of congestion of the lungs the day following the application of the cast, which cleared up rapidly when the patient was put in a wheel chair.

With the exception of one old lady, upon whom a double cast was applied, all have been in chairs daily throughout convalescence. Many of the patients became so accustomed to the cast that they could be transferred from the bed to the chair by merely supporting the leg in the cast.

Strength and general nutrition are maintained by the exercise of pushing themselves about in a wheel chair, so that when the cast is removed these patients have been ready to begin the use of crutches at once.

Immobilization with the single spica has apparently been complete in these cases, and the results have been so satisfactory and the patients so comfortable that the double spica has not been given a fair trial. The double spica or

some other modification may supplant the single spica method as used in the present series of cases, but some form of immobilization in flexion, both of the thigh and lower leg, permitting the patient to remain in the sitting posture, preferably in a wheel chair, has a definite field in the treatment of hip fractures.

#### Address.

### THE PORTRAITS OF FLORENCE NIGHTINGALE.

By MAUDE E. SEYMOUR ABBOTT, B.A., M.D.

McGill University, Montreal.

(Continued from page 421.)

#### V. FLORENCE NIGHTINGALE IN LATER LIFE. (1861-1910. PLATES XII, XIII, XIV, XV.)

Sydney Herbert died in 1861 when Florence Nightingale was forty-one years of age. She lived nearly fifty years longer, and for thirty-five of these retained the full use of all her faculties and the same phenomenal capacity for accomplishing heavy tasks in numerous fields simultaneously, each of which was, in itself, sufficient for the full powers of a single individual. His death threw her into a state of extreme despondency, for she had lost not only a dear personal friend, but the ally on whom her sanitary reforms depended. From the seclusion of a deep retirement she published a short "Life of Lord Herbert," in which she ascribes every part of their reforms to his work. Had he been writing the book he would have made the same statement in relation to herself, and in a sense both statements would have been true, so completely interdependent was their action. In ascribing the credit for all the achievements of the Crimean climax and those resulting from it, the names of Sydney Herbert and Florence Nightingale must always hold an equal place. The British public recognized this fact in the erection, in the winter of 1911, of the dual statues to these which stand on either side of the Crimean monument in London today.

Space cannot permit of even the complete enumeration of all the numerous reforms engaged in this later period of her life. Probably

the most comprehensive, and certainly that in which an immense portion of her time and energy was expended to the very end of her active life, was the improved sanitation of India,—a problem arising out of the work of the Crimean commissions, and in which she was intimately associated with Sir John Lawrence, Sir Bartle Frere, Lord Roberts, and other leading East Indians. She stood for advanced methods, brought to the evidence irrefutable masses of statistical facts, and fought desperately, among other things, for universal irrigation. She was known at the time in high quarters as the *Providence of India*. "The Indian Sanitary Commission's Report," a huge volume consisting of 2028 pages of small print, contains evidence of her work on almost every page.

In the work of the War Office again, she maintained, after Lord Herbert's death, a very intimate relationship, which in time came to assume the relation of an advisory council. This was because in many questions she had come to be considered the first expert of her time, and also because, in Sir Edward Cook's phrase, she was rightly regarded as the official legatee of Lord Sydney Herbert, and one who knew, as no one else could, the spirit of the uncompleted reforms he had projected, and the traditions which had inspired one who had held a very high place in the public trust. She was concerned in this way, not only in questions of army sani-

tation in time of peace, but in all the problems that arose in the care of the sick and wounded in the various wars that broke out during this long period, and her connection with the organization of the Red Cross Society, and the various associations formed for the care of the sick and wounded, runs like a silver thread through the story of this latter part of her life. Thus we find her, during the course of the American Civil War, writing on October 8, 1861, to Dr. Farr, that she had sent to the Secretary of War at Washington, on application, all the War Office's forms and reports, statistical and otherwise. At this time also a Sanitary Commission was appointed at Washington, which reproduced much of Miss Nightingale's Crimean work. Again, on December 18, 1861, we find her revising the draft of the commissariat and army medical stores for the projected expedition from England to Canada in connection with the Trent affair.

The inception of the Red Cross Society on an international basis owes its origin to the suggestion of a Swiss physician, Henri Dunant. In the year 1859, when the full flood of Miss Nightingale's Crimean achievements were still fresh in the public mind, the bloody battle of Solferino was fought, and the wounded lay three days upon the battlefield untended, except for the irregular ministrations of neighboring peasants. Shocked at the sight of the tragedy, and proclaiming the possibility of organized aid that the Crimean campaign had shown, M. Dunant carried the proposal to the leading European powers. "that an organization with international privileges be established for the care of the sick and wounded in war." As a result, in August, 1864, an International Congress was held at Geneva, which framed the famous Geneva Convention, on which the constitution of the present Red Cross Society is based, and which declares medical aid on the field to be under the protection of a recognized neutrality. The British delegates to the Congress were Miss Nightingale's friends, Dr. Longmore and Dr. Rutherford, and she drafted their instructions. In 1872, M. Dunant in a paper read in London, said: "Though I am known as the founder of the Red Cross and the originator of the Convention of Geneva, it is to an Englishwoman that all the honor of that Convention is due. What inspired me to go to Italy during the war of 1859 was the work of Miss Florence Nightingale in the Crimea."

In the War of 1866 between Prussia, Austria and Italy, all three of the combatants sought and obtained the assistance of Miss Nightingale and she herself joined and took part in the London Relief Association for the care of the wounded. In 1867 a gold medal was awarded to her by the Conference of Red Cross Societies in Paris, and in 1870, the Austrian Patriotic Society for the Relief of Wounded Soldiers elected

her a member. During the whole duration of the War of 1870-71, she was again plunged into ceaseless activity, for both Germany and France deluged her with correspondence. She met all demands, and rendered assistance impartially to the sick and wounded of both sides, so that in July, 1871, the French *Société des Secours aux Blessés* conferred its bronze cross upon her, and in September of that year she was decorated by the German Emperor with the Prus-

mortal a city of ancient Rome. And in writing to the Crown Princess of Prussia on hospital matters, she pleaded for clemency. "Prussia would remember," she was sure, "the future wars and misery always brought about by trampling too violently on a fallen foe." We know, alas, only too well, how sadly her assurance was disappointed. During Lord Wolseley's Egyptian campaign of 1882 she was active in organizing the female nurses who were re-

sian Cross of Merit. In spite of the strict neutrality she maintained in giving aid to the wounded of both sides, it is interesting to us, in this year of war, 1915, to know that her personal sympathies were rather with the French. "I think," she wrote on December 20, 1870, "that if the conduct of the French for the last three months had been shown by any other nation it would have been called, *as it is*, sublime. The uncomplaining endurance, the sad and severe self-restraint of Paris under a siege now of three months would have rendered in-

quested, and magnificent." And in writing to the Crown Princess of Prussia on hospital matters, she pleaded for clemency. "Prussia would remember," she was sure, "the future wars and misery always brought about by trampling too violently on a fallen foe." We know, alas, only too well, how sadly her assurance was disappointed. During Lord Wolseley's Egyptian campaign of 1882 she was active in organizing the female nurses who were re-

ing with the spirit of it than that expressed at the Eighth International Conference of Red Cross Societies in London in June, 1907, to which Queen Alexandra sent a message referring to "the pioneer of the First Red Cross movement, Miss Florence Nightingale, whose heroic efforts on behalf of suffering humanity will be recognized and admired by all ages as long as the world shall last." The resolution read: "The great and incomparable name of Miss Florence Nightingale, whose merits in the field of humanity are never

the worst possible. From a noted philanthropist came the suggestion, that at the Liverpool Work-House Infirmary, one of the most difficult institutions of all, the experiment should be tried of placing twelve Nightingale nurses in control, with a superintendent chosen from among them. The story of Miss Alice Jones, a gentle girl of high religious views, a graduate of Kaiserwerth, and later of the St. Thomas's School, who struggled and won victory among vicious patients and a difficult management, and who gave up her life in doing so,

PLATE XIV. FLORENCE NIGHTINGALE IN HER ROOM IN SOUTH STREET AT THE AGE OF EIGHTY-NA.

to be forgotten, and who raised the care of the sick to the position of a charitable art, imposes on the Eighth International Conference of Red Cross Societies the noble duty of rendering homage to her merits by expressing warmly its high veneration."

Another large sphere of activity which arose since the time and outside of the department of Sydney Herbert, was that of Work-House Reform, a movement which grew directly out of the work of the Nightingale Training School. In the year 1864, no legislation provided for the care of the sick poor in England, and an absolute lack of attendance combined with a degraded class of patients to make the conditions

is one of the romances of the history of nursing. It is told by Miss Nightingale under the title "Una and the Lion" in good words. The success won here led the way for the Metropolitan Poor Act of 1867, which was a starting-point of medical relief to the poor in England, and is to be traced to the efforts of many earnest men and women, and chief among them to Miss Nightingale.

The failure of one of her attempts, that is, of the Training School at the Lying-in Department of the King's College Hospital, is to be recorded. It is of importance chiefly today, because it led to the publication of her "Notes on Lying-in Institutions," which is to be compared to the "Notes on Nursing" in its clear-

ness and originality and the soundness of its practical applications.

The Nightingale Training School was always under Miss Nightingale's supervision, but after the year 1872, when she retired, more or less, from more active association with other forms of work, and when it was removed to the present new St. Thomas's building, she identified herself still more closely with it, and it sheds other light upon her extraordinarily many-sided character. Here again, as in her youth, we see her from the domestic side. She is in close contact with her nurses, knowing each one personally, criticising and loving, chiding and helping, always on the highest plane of prin-

stood to her in the relation of "affectionate children" or "dear sisters," who had gone out into the world to carry her gospel of what the art of nursing meant to many distant lands.

In the fullness of time, after a life so crowded with productive labor, philosophic thought, and literary activity, so rich in sympathies and affection, and so transfigured by a deep religious faith that one could scarcely imagine its equal, death came to her, three years after the Freedom of the City of London and the King's Order of Merit had been conferred upon her. To the end she counted herself an unprofitable servant, and realized only the high values of those things which she had struggled to attain.

ciple, and with a depth of personal feeling and sympathy that brought her into the closest range of influence with those whom she was trying to inspire. Every year she formulated her teaching in a hospital sermon, which took the form of a letter, publicly read to the nurses. In these days her home at South Street was always open to her pupils, whom she met here in a sense on equal terms, and all loved her dearly. Just as in her beautiful girlhood she had sat at the feet of Elizabeth Fry, and had drunk to her soul's fulfillment of the springs of that ripened humanitarianism, so in her own latter days, these daughters of her heart's best wisdom gathered about her to learn from her own lips what it was she would have them to do. As the years closed in about her, her nurses

## Industrial Accident Insurance

### RESTORING THE INJURED EMPLOYEE TO WORK.

By FRANCIS D. DONOHUE, M.D., BOSTON.

*Medical Adviser of the Industrial Accident Board.*

THE goal of the long march of civilization is industrial peace, of that social condition where, as far as human provision can do it, the specter of old age, with its industrial idleness, its economic dependence, and its quasi-charitable treatment, is eliminated, and since the peace of one nation is based on the same elements as that of another; universal peace can come only with universal content, which is dependent on the industrial peace and content of a world of workers. Industrial peace means hope, happiness, health and homes, confidence in the age of efficiency, contentment in the years of waning powers; and the community presenting such conditions is the abode of opportunity and optimism—the ideal community.

According to the latest compilations showing the operations of workmen's compensation laws in the United States, there are thirty five divisions of state and territory subject to the control of the United States in which there are compensation laws in force. This includes Hawaii, the Canal Zone, and the federal government. When we stop to consider that this enormous movement in one branch of social legislation has been the growth of only five years of this century, the fact is apparent that there is a powerful, vital, impelling force behind such legislative initiative and enactment. If we do not stop to consider being the more practical and timely enactment of such legislation, which vary in their scope, facilities and under different conditions, the present situation probably may be said to be a favorable one, stating that this social legislation is due to a growing consciousness of the value of the

RECEIVED  
BOSTON MEDICAL AND SURGICAL JOURNAL  
APRIL 10, 1908

this country that the value of the human being engaged in productive labor, or in other forms of necessary work or service, is one of the country's strongest assets. In other words, such legislation represents in part the practical application of the principles underlying the conservation-of-human-energy idea.

Employers of labor have been insured under one form or another for a long while, and by reason of this insurance, which insured the employer against trouble, a certain system of handling accident cases has grown up, based upon the desire to shunt off a claimant as easily and as cheaply as possible.

It comprehended nothing of the rights of the employee in regard to restoring his working capacity or mitigating his disability. The new compensation laws are the opposite of this because they have as an essential, the insurance of the wage-earning capacity of the employee, and anything that reduces, temporarily or permanently, the wage-earning capacity of the employee, is a proper charge against the compensation insurance.

If we accept this interpretation of the real meaning of the movement, the suggestion is then in order that in the work of administering these laws daily, sight should not be lost of the real end in view. Obviously, the philosophical genesis of the idea may be only in part written into the actual statute. For this reason, there is a sacred obligation imposed on those administering such laws, to enforce not only the provisions of the act as written, but in such manner as to make effective the causative forces behind the written provisions. This principle entails one other duty, namely, constructive administration to procure improved law, or methods, by which the basic principles of the law may be carried out with the highest efficiency.

Following this introductory statement, the question naturally arises, What are the basic principles of a compensation law? The idea may be variously phrased, but the following is presented as one way of expressing the objects to be accomplished.

*First*, Rehabilitation of injured persons, and the economic readaptation of dependents in fatal cases.

*Second*, Financial relief during the period of readjustment.

*Third*, Accident prevention.

In connection with the consideration of the problem of rehabilitation, the following are essential in laying a foundation for the proper care of every case and the earliest possible restoration of the injured employee to industrial efficiency:

(a) Prompt and efficient first aid is most important.

(b) Time is an essential requisite.

(c) Efficient hospital service.

Illustrating the importance of prompt and efficient first aid, the records at the plant of the Norton Grinding Company, at Worcester, where

first-aid work has been in charge of Dr. W. Irving Clark, there has not been a single case of infection following injury during the last five years. Every type of injury was encountered, including the most dirty, and it is perfectly evident that only prompt and skillful treatment can account for this surprising and gratifying result.

Time is a more important element than the busy physician is willing to admit. This is well shown in fractures which, if treated at once, can be more easily set, and with better after-results, than if they are allowed to wait and care is given after delay, accompanied by swelling and disturbances of circulation—conditions adding to the immediate difficulties and laying the foundation for future trouble.

After first aid, rendered promptly and efficiently, comes the consideration of adequate hospital care. Hospital care should mean efficient hospital service. We have all kinds and methods of treatment in Massachusetts under the Act. Some treatment is furnished by the insurance companies, either by men with whom they make direct arrangements or by the utilization of private or public hospitals. Free choice of physician is allowed the men in a large percentage of the cases. The first kind of treatment theoretically is the best kind of treatment, because it is presumably carried out by those more expert in the surgical care of the patient than the ordinary practitioner. A large proportion of the cases are necessarily hospital bed cases. Under the old law, which was in effect up to October, 1914, at the end of the fourteenth day the responsibility of the insured ceased and the responsibility of the man himself came in. The Legislature of 1914 permitted the Board, in unusual cases, to order the insurer to give treatment beyond the fourteenth-day period. By the payment of a little additional money now, the injured man is given continued treatment after the fourteenth day, and he is restored to industry more quickly and in better condition than if thrown upon his own resources at the end of the two weeks' period. Giving a man hospital care for the first fourteen days, and then discharging him to the resources of a home from which the pay envelope has been absent for two weeks, and compensation payment is not due for seven days more, can hardly be called ideal.

From our standpoint, the efficiency of hospital management is not represented by the purchasing price of provisions, the purchasing price, perhaps, of milk, or the utilization of medical and surgical supplies to the best advantage and at the lowest cost. Hospital efficiency, from our standpoint, should be represented firstly by the time it takes to restore a man to work, and secondly the end-product that the hospital furnishes in the line of a good workable result.

Dr. E. A. Codman of Boston has pointed out in a study of efficiency which he has made, "that

no good factory neglects careful supervision of its end products, and it is perfectly evident that the state or city, and the citizens who by private gifts or by way of the tax office make possible and support these huge plants, have a right to know what they are producing and what the actual end result in actual benefit is."

Every compensation board should strive for a measuring of end products, represented by the time taken to complete a cure and the amount of disability represented by the difference in wage-earning capacity of the employee when he is back on his job. It may be possible that hospitals may be grouped according to their end products, and weekly payments allowed on the basis of hospital efficiency. Is it not our duty to the workman whose future depends upon the treatment given, and to the community which depends upon the worker, to strive for better results?

Many authorities have claimed that compensation and other forms of social insurance have led to a destruction of the ethical standards. It has been claimed as a result, "malingering has increased, traumatic neuroses, so called, have been fostered," and that "the number of claims for illness has increased out of proportion to the number of insured." If that has been true of England and Germany, it has not been the experience in Massachusetts under the Workmen's Compensation Act.

In three hundred consecutive examinations of disputed cases under our Act, I did not find a single deliberate fakir. These cases were, however, mostly adult workers with wage-earning capabilities far beyond the compensation. There is a tendency, however, in three well-marked groups not to minimize the results of accident or injury. They are, however, a small per cent. of our totals.

The first group is composed of the men in what may be called the twilight zone of life,—the ages above sixty. Here the man is arriving at the end of his strenuous working days. His vital forces are running down, changes are occurring in his circulatory system, and the organs and tissues depending upon it for their upkeep. He professes to be as good a man as he ever was, but he is not keeping the stride with the younger workers. Perhaps he has been obliged to take a lighter or a different job than he formerly was able to do. This man when knocked out of his working stride by injury is hard to patch up.

The second group is made up of the regular drinkers. Dr. William J. Brickley, of the Boston City Hospital Relief Station, has made an interesting contribution to the literature of the subject. This represents a study of about 40,000 cases a year over the second year. It may be stated, based upon his experience, which Mr. Holman has given you in some detail and which I wish to emphasize, that:

- a. Alcohol causes accidents.
- b. Alcohol obscures the diagnosis.

c. Alcohol increases the danger of infection at the time of the accident.

d. Alcohol prevents adequate treatment.

e. Alcohol increases the danger of inter-current complications.

f. Alcohol retards the process of repair.

g. Alcohol gives a poorer end result.

h. Alcohol increases the mortality in accidents.

It is enough to refer only to the figures in accident cases which resulted fatally. "During the years 1911 to 1914, inclusive, there were 658 fatal cases at the hospital, and of the adults who died because of the accident, 40.6% were under the influence of alcohol when they were received for treatment." The condition of alcoholism contributed materially to the fatal termination of these cases. The presence of saloons in the manufacturing districts is a well-known and apparent danger. The eleven o'clock, or later closing hour, in the home district of the worker, is even a greater danger.

It would seem that saloons, if permitted in residential districts, might have a closing hour not later than 9 o'clock and the opening not earlier than 8 in the morning. Labor exchanges are necessary adjuncts to compensation rehabilitation. In properly organized exchanges, intelligent labor union cooperation will be found most desirable. In Massachusetts the labor leaders, including the much-abused "walking delegate," have not only rendered the greatest possible assistance in the problems of reemployment, but in many instances have been of the utmost importance in aiding in the determination of the rights of injured employees or their dependents.

Do not underestimate the value of the aid that unions can give. They have members trained in fraternal societies, as well as in the union's administration of sickness and accident benefits for years before either was considered necessary by the community at large. There would be increasing aid from "union" sources if their members were fully informed that in protecting and helping others their own rights would be safeguarded.

The idea that cases have a "lump sum value" is a distinctly bad one. It is open to the objection that an employee does not make his best effort at work resumption or readjustment, either through his own volition or because encouraged by legal advice, for settlement of a lump sum a lawyer could often get for him. It may be open to abuse on the part of the compensation payor, or the claimant, or the attorney, or the "ragged" or "tender" or the "charity" or as a labor Nerve Center, or the "lump sum" lawyer, or the "lump sum" doctor. It should be carefully guarded against.

Unless the method of treatment employed represents the value of the injury, that kind of medical sum is better than no sum at all, and is entirely adequate for the purpose of relieving the patient from the financial burden of the accident.

injured workman and his claim for compensation are openly encouraging; and the employers cooperate by providing jobs for the man during the process of rehabilitation, the real end of compensation will not be attained.

*Hospital Records.* On hospital records, in some degree, depend the rights of the injured or of his dependents. Are adequate hospital records available outside of the larger institutions? Do surgeons operating in private hospitals keep proper narratives from which cause and effect might be deduced? What of the surgeon who is permitted to take a case into a large hospital and treat it as a private case, and be free from obligations as to technic and records incumbent upon one with official position? And what of the record kept by the ordinary man as he runs along? Let me ask, is it possible for this body, which has in some measure the control of "medical purse strings," to act in conjunction with the committee of the American Medical Association and with the State societies in furthering this important movement for efficiency?

*Social Service or Follow-up Treatment.* Social service, in conjunction with a compensation board, would bring greater returns for the expenditure than in any other form of medical conservation. As an adjunct to a hospital, service which should investigate the home or lodging to which a man is discharged, to learn why he does not return for treatment; and to aid in bringing treatment to him if he cannot come after it himself. Thousands of dollars are lost to the insuring companies representing the employers, and more thousands are lost to the injured man, by depending upon the impersonal and hurried treatment of the crowded hospital out-patient department. Poorly-kept records, no follow-up treatment, and no end results, mean slow return of wage-earning capacity if full recovery ever comes.

*Institutions for Crippled Workmen.* The methods employed by the warring nations of Europe in restoring the crippled products of war, either for military or civil purposes, contains a great lesson which we may take and apply to the injured workmen in the battles of peace. The modern institution for crippled workmen should be quite a different institution than an institution for the care of the ordinary sick, or for those suffering from ordinary medical illness or surgical disease. We need a combination of the methods found useful in the restoration of children with the surgery found useful in the restoration of adults. Medical specialists, orthopedic mechanics and various classes of artisans and professional people, who should be called upon as teachers, and all of whom should be near at hand and readily available, are essentials. Such institutions should be erected in all large industrial centres. An uncongested locality with plenty of air and sunshine, which has been considered of importance in the treatment of bone tuberculosis and the

diseases of malnutrition of children, is not necessary for adults suffering from industrial maiming. Adequate food, adequate bed facilities, and adequate medical mechanics are more important than sunshine and country.

Orthopedic surgery as a specialty is of fairly recent growth. Up to a comparatively recent time, it was a department of general surgery, and the general surgeon was the man who did the work. With the broadening of the field of the general surgeon, surgery naturally underwent a sub-division, as it was not possible for one man adequately to cover the entire field. Restoration of function in many cases is purely a question of medical mechanics. Is it being properly solved by the surgeon?

The next step in the coordination of educational forces will be to secure the coöperation of all those hospitals and training schools which have been so useful in the care of crippled and deformed children, so that their experiences and plants may be devoted to the reëducation of the injured workmen.

Permanently disabled employees present a distinct and separate problem, which has not yet been met successfully in any state of the Union. In Massachusetts every year, between 400 and 500 cases annually are reported in which the injured employees are incapacitated for work for a period of upwards of one year. During the third year of the Act, 421 such cases were reported, and search finds at least that many cases of permanent partial disability upon the lists of insurers, with many cases running into the second and third years, and some passing through the entire period of 500 weeks during which compensation is payable, if the employee is in fact unable to earn wages by reason of incapacity due to the injury.

It is not a high estimate to place the figures for such incapacity at 421 cases a year, and the rate of compensation at \$8. During the first year of the Act the cost of such cases may be assumed as \$175,136. During the second year the cost must be increased by 50% to allow for cases which have been carried from the first year. This figure is \$262,704. During the third we shall assume that the second year's figures have not been increased and add \$262,704 to the cost of compensation, making a grand total of about \$700,000 for the first three years of the Act. This cost undoubtedly is low and has been purposely kept low for the reason that we do not wish to base our claims upon a false premise.

At least 50% of this compensation cost can be saved by the intelligent supervision of the work of rehabilitating injured employees. The cost for such supervision and the working out of the plan would be low, after the first outlay had been made. Probably it would be self-supporting, and certainly the results would prove alluring to insurers. One-handed and one-armed men, and even the blind, can work, if such work as they can do is furnished them. A thorough canvass of the industrial establish-

ments of the Commonwealth, and the listing of all work that one-armed men can do, will help to reduce the number of such men from the compensation lists of insurers. Work that one-legged men can safely perform also can be listed, and these men can be taken off the compensation rolls and put on the payrolls of the employers of the state. The same process can be followed with one-eyed men, until every possible job suitable for crippled workmen is secured and placed at their disposal. The small balance can be taken in hand and trained in the performance of certain special work, furnished with the very best artificial appliances and made ready for their place in industry.

In countries at war, plans are being worked out for the reëducation of crippled men which can be adapted to our needs here, by the use of the resources which are at hand, and the addition to such resources by the erection and maintenance of plants which shall be used for that purpose.

His Excellency, Governor McCall of Massachusetts, has set the seal of his official approval upon the movement to reduce occupational diseases and accidents to a minimum, and in an especially able message to the Legislature has recommended that all the powers under the existing laws be reposed in the Industrial Accident Board for the accomplishment of this object. If the Governor's recommendations are adopted, the power to direct and enforce safety rules and regulations, and the rate-making power in so far as compensation insurance is concerned, will be under the sole jurisdiction of the Board. His Excellency shows that he has an intimate knowledge of the problems of accident and disease prevention, and that he believes the cost of insurance can be kept down to a reasonable figure by the intelligent control and supervision of this work by a responsible state commission.

When we put the Workmen's Compensation Act into effect, we learned the lesson from the Old World. The principle and administration of it represented at once justice, industrial peace and applied Christianity. It set up a flag of truce between capital and labor, and had the employer and employee join hands in a common cause of good. It incorporated into law the Christian principle that man is more than material, and one of God's creatures, made in his image and with a soul, must be treated in accordance with the dignity of his place in the economy of the universe, and not to be bought and sold and put aside when used up. In carrying out the law, let us arise to the opportunity offered to do good, and care properly for the crippled by-products of industry, just as pathetic and infinitely closer to us than the poor victims of the war across the sea.

Let us see to it that these men, working with us for a common country and a common humanity, are given such care that their broken hands, maimed limbs, shall no longer lead to

despondency or despair, but by our efforts aid in making their hardships and handicaps aids to happiness, and their lives made more useful and contented by being able to work. Massachusetts, through its progressive Industrial Accident Board, has accomplished much. If we can keep true to our ideals, we will delight in more and more satisfaction in knowing we have saved our unfortunates from the misery of idleness, the stigma of pauperism, and the humiliation of dependence.

NOTE.—Dr. Donoghue's remarks were illustrated by fifty lantern slides, showing the re-education schools and the reeducation methods being used for the European soldiers.

## HOSPITALS AND WORKMEN'S INSURANCE\*

By F. J. COTTON, M.D., Boston.

*Visiting Surgeon, Boston City Hospital.*

I do not care to go into the rate squabble between insurance companies and hospitals as such. This matter is unpleasant, and at any rate is not finally settled, nor likely to be for some time. If you wish, I'll tell you what I know of it, out of more experience than I wish, afterward; but first it will be wiser, perhaps, and certainly more pleasant, to consider what the broad general movement for compensation means, and what its relation is to that other country wide movement, in the medical profession, for the furthering of hospital efficiency. This movement is of just about the same age as the Compensation Act in this Commonwealth. Let me hasten to add that I believe these movements in no way antagonistic, but mutually helpful; both details in the march of social progress; both good, however much each may tread on individual prejudices or even rights, at times.

I am afraid that until lately we have not realized certain defects of our hospitals, have not searchingly criticized ourselves—or sought or tolerated outside criticism.

What has been called the manufacturing product—our end results—we have not yet known and this applies to all of us in our activities.

Now comes a Workmen's Compensation Act not previously aimed at its cost to employers but so framed as to make it certain that the provisions are obvious because they are all in the interests of the insured. The bill concerns the insurance covering the cost of a dollar every 40 hours.

nerve involvements are common in limb injuries; that fractures of the spine are not rarely overlooked, if the cord is not damaged.

These things we did not know clearly before, but it was largely not our fault. There was no way we could know; no machinery for getting at end-results available to us. That the present situation helps us in our search for knowledge strikes me as fortunate; not anything to get peevish about.

I wonder how many of you know that our own accident board has promised the fullest co-operation in tracing our end-results, in our cases coming under the Act; even offering services of inspectors in tracing? Or that our superintendent, Dr. Dowling, is having his "Centre" data so gathered and kept, as to be able, presently, to take advantage of this favor? In fact, there is already one investigation going on, soon to be ready, under co-operation of the board and certain members of this and another hospital staff, as to results in one of the less understood classes of injury, above noted.

Certainly no one connected with a hospital wants to give less than the best possible work, under the given circumstances. Now criticism of results proves in fact only rarely criticism of personnel. It is criticism of our hospital methods; of methods partly due to money stringency, but more due to tradition from a time when the hospital did not perform the service to the community that it does today.

Not far back, the hospital was a place for desperate illnesses and courageous surgery. Then if a man got well at all, he asked little as to weeks spent. Now, with the progress toward perfection in medicine and surgery, much that was daring and experimental has become routine. It is no longer notable that an appendix case gets well, or that a hernia holds after operation; it has become, rather, a question why John Smith is not ready for work eight weeks after such an operation, instead of in six, as we have educated folks to expect. And we have not yet perfected our machinery to meet the increased refinement of our practice. We must not only do well by the patient in the operating room, but we must study him beforehand and see him through afterward, until he is fit to go back on the job, if we care to measure up to our new standard of efficiency.

Not a hospital in the country is up to this standard today. This standard means, for one thing, that the medical nursing and other personnel of our out-patients must come up, in the next fifteen years, as much as the personnel and the perfection of work done in our operating rooms has come up in the last fifteen.

None of us can measure up to this standard today, but we can at least see clearly what it is we have to strive toward, and work in the right direction. In order that we may do this, the first requisite is that we should be able to measure our finished product; to know what results we are getting. And I have preached for a good

while that there is no one way of measuring results so definite as the getting of a man back to his normal connection with his weekly pay-envelope. It is just this test that the Workmen's Compensation Act enables us to have, and when we have our results, I think we should rest content to have them stand open to inspection.

There can never be a single fixed standard for all hospitals, public and private, big and little, but if the finished product of all were known and visible, there would be no trouble in knowing how they were fulfilling their function; in making any necessary allowances for difference in the communities and classes and industries served, etc., and in bringing up inefficient units. The difficulty in so bringing up ineffective units is mainly in defective organization, but it is also a matter of men. Hospital service has been, in our time, a matter of volunteer service; the service given has been of the highest quality, but the time for giving it often restricted and sometimes irregular, as must happen in the very nature of the case with volunteer service.

In the development of hospitals along efficiency lines, closer organization will be essential; more method; more clerical, nursing and orderly work; probably a force of young medical men, under salary, combining into a whole machine of some permanency. Dependence upon volunteer student work is already almost a thing of the past.

And here we meet again the Workmen's Compensation Act. All this development means money for hospitals. And workmen's compensation means, or should mean, money for hospitals.

This is another side of the matter. In the past the hospitals, great and small, have devoted themselves to the care and cure of the poor devil, without question of his status. Now he has become a real financial factor, and his restoration to health a real asset to the insurer. We are rendering services to the company as well as to the poor fellow himself, and the company should help; unless, indeed, one can see why the employer should pay the company to cover medical expenses on the one side and contribute on the other, in endowment, gift or yearly contribution, or in taxes, to support a hospital to do the same work. There seems no question about the principle; there is some question about the law, and the insurance companies have, perhaps not unnaturally, been somewhat less than liberal in their desires as to the construction of the law. The argument has been that the hospital always did this work without pay; why not continue? This is specious at best, but the reply is obvious; not only in that it is an injustice to the employing class, as above noted, but also in that new standards are being demanded by the hospitals and their doctors, as well as by the public: that better work means better equipment, and the insurance company, which profits, should pay.

Personally I believe, and most, at least, of our State Accident Board believe that there is a real economy in the end in better work, but owing to difficulties in getting data, this is hard to reduce to figures.

We believe the insurance companies will save money by paying for more and longer care. Many insurance men believe this, too, which is why there was so little opposition to the amendment to the Act I had the honor to prepare two years ago. The amendment is now in effect providing for care continued beyond the two-week limit, in cases unusual and intrinsically serious. This means that the insurer accepts his responsibility for cure and care, as well as maintenance of the injured man, in some cases. The original law contemplated only the two weeks of assured medical care, and that is enough in most cases. Already, however, insurance companies are paying for continued care in many instances; for repair operations later in many others.

In time I trust we shall see them assume all medical care in some form. But we must not be greedy about it. The real obstacle to progress along this line in Massachusetts is the enormous percentage already reached by the medical expense.

### Book Reviews.

*Rules for Recovery from Tuberculosis.* By LAWRENCE BROWN, M.D. Philadelphia: Lee & Febiger. 1916.

This little book, coming from such an authority as Dr. Brown, will fill a distinct want in the literature on this subject. Although several other volumes, for the same purpose, have been written, this book of Dr. Brown's is different, in that it goes into more detail, and discusses the various problems in a less elementary manner than do the others. This very fact leads to the only possible criticism which can be made of this book, in that the class of patients who can really grasp and understand the detailed and scientific advice here given is limited.

At Saranac Lake, this type of patient is, of course, much more common than elsewhere. In large cities, and in the majority of large state or municipal hospitals and sanatoria, the patients whose grade of mentality would enable them to profit greatly by what Dr. Brown has written, are not anywhere near as numerous. For them, shorter books, giving advice and information in a more definite and categorical manner, might be preferred to this of Dr. Brown's. To those patients, however, who can really appreciate what this book contains,—and these naturally are the ones for whom the book is intended,—this volume offers everything that can possibly be desired in the way of a *rad. medium* for consumptives.

The chapter on tuberculin is one with which the average patient has comparatively little concern. The chapter on diet, likewise, discusses the chemistry and physiology of food values in a way which would be quite beyond the majority of patients at any large public sanatorium. The chapter on climate is full of common sense. There is an excellent chapter on the care of children in the homes of the tuberculous. There is an excellent chapter on controlling the cough without drugs. A list of other books and pamphlets on the same or allied subjects, and a detailed index, are valuable additions. On the whole, the book is a very valuable one, not only for patients, but for many physicians to read and study.

*A Textbook of Practical Gynecology for Practitioners and Students.* By D. TOD GILLIAM, M.D., and EARL M. GILLIAM, M.D. Fifth revised edition. Illustrated with 352 engravings, a colored frontispiece and 13 full-page half-tone plates. Philadelphia: F. A. Davis Company. 1916.

This book is now issued in a so-called fifth edition. Strictly speaking it is only a reprint of the fourth edition, for the changes are a name on the title page, an additional date of copyright, a few words in the preface and a few paragraphs in the section on disturbances of menstruation. Otherwise it is almost an exact reprint of the fourth edition, page for page, line for line, letter for letter, but on inferior paper. As a reprint, then, it needs no additional review. It has the same good qualities and the same defects as before, except that if there has been any progress in the past five years, Gilliam's textbook does not contain an adequate account of it.

*Manual of Vital Function Testing Methods.* By WILFRED M. BARTON, M.D., Associate Professor of Medicine, Georgetown University. Boston: Richard G. Badger. 1916.

Prior to the publication of the present volume the literature of functional tests has remained widely scattered in medical journals. In Dr. Barton's work this material is, for the first time, gathered into a single book which deals not solely with the methods of these vital function tests, but with their significance and interpretation. The tests are classified according to the organs whose function is under consideration, namely the liver, kidneys, pancreas, heart, thyroid, suprarenal and intestines. They are classified and their technique described in detail, with a series of sixty fourteen references of the literature from which further details may be obtained. The book would be of value and interest to general clinicians, not to clinicians, as well as to special students of physiology and endocrinology.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, SEPTEMBER 28, 1916

## EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*  
GEORGE C. SMITH, M.D., *Assistant Editor.*  
WALTER L. BERRAGE, M.D., *For the Massachusetts Medical Society.*

## COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D.  
HARVEY CUSHING, M.D.  
DAVID L. EDSALL, M.D.  
REID HUNT, M.D.  
ROGER I. LEE, M.D.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, \$6.50 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager,*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## INDUSTRIAL INSURANCE AND WORKMEN'S COMPENSATION.

THE subjects of industrial insurance and workmen's compensation constitute important present points of contact between legislation and the medical profession, since the rights and interest of physicians, as well as those of workmen, insurance companies and employers, are involved in their provisions and application. They are subjects of relatively recent origin, and in their establishment and development certain details have as yet not been satisfactorily adjusted. During the past few years the JOURNAL has from time to time published articles by well-known members of the profession, bearing on various aspects of the problems involved, and has commented editorially upon them, endeavoring always to maintain an open and impartial point of view, seeking only to determine, through discussion, what may be most judiciously fair and mutually advantageous to all the interests concerned.

In the issue of the JOURNAL for September 21 was published, with editorial comment, an article by Dr. Francis D. Donoghue on "Some Medical Aspects of the Workmen's Compensation Act in Massachusetts." In the present issue is published a further article by the same author on "The Restoration of the Injured Employee to Work." Particular attention is directed to a paper by Dr. F. J. Cotton, also published in the present number of the JOURNAL, dealing with certain of the questions which have arisen with reference to hospitals in the administration of the Workmen's Compensation Act. Finally, in the correspondence column of this issue of the JOURNAL, is published a letter from a committee appointed by the Middlesex North District Medical Society to investigate the Workmen's Compensation Act in its relation to the medical profession. This letter gives expression to a growing dissatisfaction on the part of general practitioners of medicine with the application of the Act, especially with its forbidding the injured workman to select his own physician. The letter is earnestly commended to members of the Massachusetts Medical Society, and to other readers of the JOURNAL for careful perusal. There is also published a letter by Dr. Merrill, of Lawrence, criticizing a previous editorial of the JOURNAL on this subject.

The meeting, to which reference is made in the latter part of the former letter, notice of which was published in the issue of the JOURNAL for September 14, was duly held in the Hotel Bancroft, Worcester, at 11 a.m., Sept. 20, and attended by about 75 delegates, from all but one of the districts of the Massachusetts Medical Society, and from the Massachusetts Homeopathic Medical Society. After effecting a temporary organization, the meeting elected Dr. William H. Merrill of Lawrence as its chairman, Dr. George O. Ward of Worcester vice-chairman, and Dr. Joseph A. Mehan of Lowell secretary. After discussing the purposes for which it was summoned, the convention unanimously adopted the following resolution:

"It is the sense of this convention that the Workmen's Compensation Act is unfair to the workmen and physicians of Massachusetts, and should be amended so as to give the injured workman the right to select his physician, surgeon, hospital, or all three, without sacrificing any of the benefits accruing to him under the Act; furthermore, the associations should be responsible for the expenses of medical, surgical

and hospital care during the first two weeks after injury, and, if the employee is not immediately incapacitated thereby from earning full wages, then from the time of such incapacity and in unusual cases, in the discretion of the Industrial Accident Board, for a longer period."

It was also voted that each delegation should report the action and recommendations of the meeting to its district society for consideration, and that a sub-committee of nineteen should be appointed, consisting of one representative from each of the eighteen districts of the Massachusetts Medical Society and one from the Massachusetts Homeopathic Medical Society, to hold further meetings and discussion. The membership of this sub-committee will be announced in a later issue of the JOURNAL, in which it is expected that a more complete report of the proceedings of the meeting will be printed.

It is obvious that there are conflicting interests in the application of the provisions of the Workmen's Compensation Act, but it is our belief that these interests can and will be adjusted and reconciled to their mutual best advantage. The merits of the points at issue are not as yet wholly clear. During whatever discussion and legislative action may ensue, the columns of the JOURNAL will welcome, and will remain freely open to, communications from the various parties concerned; and editorially the JOURNAL will endeavor to maintain a temperate and judicial standpoint, which may facilitate an early and satisfactory settlement.

#### MOTION-STUDY FOR MORE EFFICIENT OPERATING.

Do we need a standard hospital, with instruments and methods based on scientific study, that shall serve as a model to medical students? Magazines and the daily press have told us of Mr. Frank B. Gilbreth, who has been studying the motions of the expert type-setter, the lathe-worker, the pianist, the typist and the surgeon, by means of the stereoscope and the cinematograph. The stereoclinic of Dr. Howard A. Kelly has made the operative technic of various surgeons familiar to the profession. Now comes Mr. Gilbreth in a letter to the September 9 issue of the *Literary Digest*, in which we find these statements:

"After visiting some of our most prominent hospitals, we found that the surgeons could learn more about motion-study, time-study,

waste-elimination, and scientific management from the industries than the industries could learn from the hospitals."

"In studying these many hospitals we find the conditions, as a rule, much worse from an administrative standpoint than in the average factory, and some hospitals are so bad that they should be actually closed immediately."

"The tools of the surgeon have not been standardized in any satisfactory way. Any mnemonic classification made of the tools of a hospital shows that the tool situation is positively pathetic and ridiculous, this present state being the outcome of the incentive which ever exists to design special tools. This condition can be realized only by subjecting the present tools to the tests of motion-study."

"Great practice with comparatively few tools is one of the laws of the most efficient use of tools. How does this compare with the custom universally present in surgery today? The average doctor usually considers that the possession of specially designed tools is a desirable asset. The constant incentive under present conditions in surgery is to design more tools, since the designer receives credit from the public, and sometimes also from his coworkers, and occasionally has the honor of having the new tools named for him. Naturally, the greater the number of tools the less must be the practice with each; the smaller becomes the chance of having a standard tool which is used by all. The general tools of the hospital are by no means as carefully selected as are those of the trades and factories. There should be one central, specially equipped laboratory for measuring, testing, and comparing all new designs with existing standards."

Mr. Gilbreth states further that equipment and surroundings must be subject to the same process, and that motion-study standardization in no way interferes with the other processes of the surgeon or his clinic, and he asserts that even at this early stage of his investigation he can save more than 10% of the time that the patient is under ether in the average operation, without "speeding up" the surgeon. He says:

"How do we determine these motions? We subject them to measurement. First, by dividing activity into its various functions. Then, we number the work of the surgeon, as he does it, among the super-skilled, and it can be determined exactly where motions are duplicated, and which of his motions are to be discarded."

"Having determined exactly what work is necessary, the elements may be combined to show how this work may be done in the most efficient manner. The result is the standard."

The surgeon of experience will recognize in Mr. Gilbreth's plan a step in advance; he remembers how, as a student, he groped in the dark for the essentials of operative technique; how each surgeon had his specially constructed instruments for special operations; how the plan of operating depended on the whim of the operator, rather than on a standard derived from combined experience—individualism rather than common training. Furthermore, the thought has come more than once to the spectator of the operations of the surgical putterer, as the valuable minutes are wasted in the refinements of almost endless minutiae, that the boon of anesthesia to suffering humanity has been sensibly diminished by the overconscientious operator. Better the pre-anesthetic days, when the surgeon was forced to do the absolutely necessary in the shortest possible time.

Obviously, the fit should become the operators, rather than those who decide that operating suits them, or those who detect the rewards lying in that field. One does not like to look back over a long surgical career and remember the bad surgery he has witnessed by the overconfident, the poorly trained and the unfit. If Mr. Gilbreth's motion-study will help to winnow out the superskilled so that they may be recognized by all it is to be welcomed by the profession.

#### LEGISLATION ON POLIOMYELITIS.

DURING the past week the epidemic of poliomyelitis has continued to decrease in New York and New Jersey, and has remained essentially stationary in New England. On September 23, the number of cases in New York City reached a total of 8885 with 2233 deaths. In New York State, outside New York City, the number of cases on September 22 reached a total of 3087 with 551 deaths.

In Illinois, from July 1 to August 31, 415 cases with 38 deaths were reported, and in New Jersey, from August 29 to September 5, 401 cases were reported. The total number of cases in New Jersey since June 30, 1915, is 2,878.

In Massachusetts, on September 24, the number of cases since September 1, reached a total of 424,—34 more than were reported during the first eight months of 1916. Outside of Boston

the largest number of cases is in Holyoke, where on September 24 there were 60 cases, of which 42 had occurred since September 11. There are cases in every one of the 36 cities of Massachusetts except Attleboro, and in 149 of the 318 towns. In the 1910 epidemic 153 towns were involved. The opening of Boston schools has been postponed to Oct. 2. In Rockland, Me., on September 16, 25 cases and 11 deaths had been reported. There have been 683 cases in Connecticut, 101 in Rhode Island.

In Massachusetts, on September 14, Governor McCall sent to the General Court the following message calling the attention of that body to the necessity of legislation empowering local boards of health to establish quarantine measures against poliomyelitis and recommending the passage of an emergency measure to provide such authority.

"It has come to my attention that there is doubt whether the power of the boards of health to quarantine against a spread of communicable diseases is sufficiently strong to enable them to take measures which may be necessary to check the spread of the disease known as infantile paralysis. While I am informed that the general subject of extending powers of boards of health with reference to communicable diseases has been the subject of investigation by legislatures and may require more careful study than can be given at this time, I think that as an emergency measure, to aid in checking the spread of infantile paralysis, the powers of boards of health, if not adequate, should be enlarged until such time as the danger of an epidemic during the present year shall have passed, or until the next Legislature shall have had an opportunity to study more carefully and pass upon the subject in question.

I recommend the passage of legislation to that end."

From the Committee on Public Health, Senator Clark of Brockton forthwith reported a measure known as the Bates Bill, based on the Governor's recommendation. This bill was immediately passed to be engrossed and was promptly signed by the Governor. The text of the Bates Bill is as follows:

"Section 1. Boards of health in cities and towns, or boards of selectmen in towns, may make such rules and regulations as are necessary and proper to check the spread of the disease known as infantile paralysis, and to cause its eradication by quarantine or otherwise.

"Section 2. The state department of health shall have the power to revoke or revise any such rules or regulations when they are unnecessary or unreasonable, and all such rules or regulations shall not have force or effect after Jan. 15, 1917."

Apprehension has been expressed in certain quarters that the increasing number of cases of poliomyelitis in Boston may overtax the capacity of local hospitals. As a matter of fact there seems little likelihood of this contingency, but should it occur, there is possibility of adequate accommodation by employing the facilities of the quarantine station at Galloupe's Island which have been offered to the city by Dr. S. B. Grubbs of the United States Public Health Service in the following recent letter:

"When the epidemic of infantile paralysis first began in New York City, I called at the city health department and offered the use of the hospitals on Galloupe's Island to the limit of our capacity (eighty beds), in case they should be needed. In view of the increased number of cases in Boston, I wish to renew this offer to you. As per the existing agreement and my official instructions, these cases will be taken at \$1.00 per day, the city to furnish a sufficient number of nurses.

It will be possible also for us to take care of a considerable number of contacts, or members of the patients' families, if this is desired by the health department, and for these the charge would be the actual cost of provisions furnished, plus twenty-five per cent., which would not be over fifty cents per day."

### MEDICAL NOTES.

**BUBONIC PLAGUE AT BRISTOL.**—In the issue of the JOURNAL for September 7, we noted the recent occurrence of three cases of bubonic plague at Bristol, England. The weekly report of the United States Public Health Service for September 8, notes the occurrence of two further cases of plague at Bristol, and one at Hull, England.

**VENEZUELAN LEPROSARIA.**—The weekly report of the United States Public Health Service for September 8 contains the following note on leprosy in Venezuela.

"Two leprosy hospitals are in operation in Venezuela. The larger is on the isla de Providencia, situated just outside of the harbor of Maracaibo. It can accommodate 700 persons, is provided with steam laundry and steam apparatus for disinfection of clothing and bedding, and is in charge of a corps of physicians and nurses. The lepers received represent every class and period of life, and every stage of invasion of the disease. They are segregated in the several States of Venezuela as they are admitted, and later removed to the isla de Providencia.

At the beginning of the year 1914 there were 400 inmates at the leprosarium, and during the year 233 were received. During the same period 10 patients were discharged apparently cured.

The leprosarium at Cape Blanco, situated about 4 miles from La Guaira and Maiquetia, was formerly operated to its full capacity of 400 persons, but was later closed. It is now used as a temporary leprosarium for lepers from the vicinity, who are there cared for until transferred to the isla de Providencia."

**AMERICAN ASSOCIATION FOR CLINICAL RESEARCH.**—The eighth annual meeting of the American Association for Clinical Research is to be held in New York City on September 28, 29 and 30, under the presidency of Dr. Daniel E. S. Holman of New York. The secretary of the Society is Dr. James Krauss of Boston.

### EUROPEAN WAR NOTES.

**AMBULANCE FOR RUSSIAN RED CROSS.**—Report from Petrograd, by way of London, states that on Sept. 20, a motor ambulance was formally presented to the Russian Red Cross by American and English women resident in Petrograd. The ambulance was sent to the front on Sept. 21.

**WAR RELIEF FUNDS.**—On Sept. 23 the totals of the principal New England relief funds for the European War reached the following amounts:

Secours National Fund .....	\$213,156.67
Belgian Fund .....	153,171.79
French Wounded Fund .....	120,320.00
Armenian Fund .....	66,772.10
French Orphanage Fund .....	62,580.19
Polish Fund .....	43,979.67
Belgian Tobacco Fund .....	37,104.09
Italian Fund .....	25,153.54

### MEXICAN NOTES.

**ARMY HOSPITAL TRAIN.** Report from Hot Springs, Ark., states that on September 10 the United States Special Army Hospital Train arrived at that city, bringing from Fort Houston, Texas, 151 sick guardsmen and regulars from the Mexican border to the Army General Hospital at Hot Springs.

**ARMY MORBIDITY STATISTICS.** Report from Washington, D. C., on September 11, states that for the week ended September 9, the percentage among National Guardsmen at the Mexican frontier was only 1.91 with 106 deaths, one each from appendicitis, pneumonia and gastric ulcer. For the preceding week morbidity was 1.92 with no deaths. As for regular troops the corresponding figures were 2.15 with four deaths and 284 deaths.

**TYPHUS AND YELLOW FEVER.** Report from Washington, D. C., on September 11, states that there has been no reported case of typhus or yellow fever in the United States since the amount of cases in the United States. At the same time, the report states that the percentage of rigid gastroenteritis in the United States is being observed.

## BOSTON AND NEW ENGLAND.

**THE WEEK'S DEATH RATE IN BOSTON.**—During the week ending Sept. 23, 1916, there were 229 deaths reported, with a rate of 15.70 per 1000 population, as compared with 171 and a rate of 11.91 for the corresponding week of last year. There were 51 deaths under 1 year, as compared with 46 last year, and 55 deaths over 60 years of age, against 44 last year.

During the week the number of cases of principal reportable diseases were: measles, 8; diphtheria, 45; scarlet fever, 15; typhoid fever, 12; whooping cough, 13; tuberculosis, 60.

Included in the above were the following cases of non-residents: diphtheria, 16; scarlet fever, 4; tuberculosis, 4.

Total deaths from these diseases were: diphtheria, 3; scarlet fever, 1; tuberculosis, 22; whooping cough, 2.

Included in the above were the following deaths of non-residents: diphtheria, 1; scarlet fever, 1; tuberculosis, 1; whooping cough, 1.

**EVENING CLINIC FOR DISEASES OF THE NOSE, THROAT AND EAR.**—The Boston Dispensary opened on September 25 an evening laryngological clinic, under the direction of Dr. H. J. Juglis. A small charge is made in order that the clinic may be self-supporting. The dispensary now maintains evening clinics for eye diseases, genito-urinary diseases, and a dental clinic.

**GRADUATION OF NURSES AT BROCKTON HOSPITAL.**—The Brockton Hospital, on September 14, graduated from its training school seven nurses. Dr. David Seannell of Boston made an address.

**FLOATING HOSPITAL.**—The last trip of the season of the Boston Floating Hospital was made on September 16. Patients too ill to be discharged were transferred to other hospitals. In the evening graduating exercises were held and 45 nurses were given diplomas.

**HOSPITAL BEQUESTS.**—By the will of the late Lyra Brown Nickerson of Providence, R. I., the Rhode Island Hospital has received a bequest of \$5000.

The will of the late Mrs. Henry Augustus Turner, of Brookline, Mass., which was filed on Sept. 19 in the Norfolk Probate Court at Dedham, Mass., contains bequests of \$5000 each, for a free bed, to the Portsmouth (N. H.) Hospital and the Children's Hospital, Boston.

### Miscellany.

#### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR AUGUST, 1916.

INFANTILE PARALYSIS has overshadowed in interest all other communicable diseases during

the month of August. Another striking fact is the sudden drop in the number of cases of measles being reported.

**Prevalence.** Communicable diseases were reported in slightly greater numbers during August, 1916, than during the same month in 1915. However, there was a marked drop in the total of reported cases of diseases dangerous to the public health, as compared with July, 1916. This was due to the sudden cessation of the epidemic of measles, which has been prevalent in the State for some months.

The following figures will be of interest:

MONTH	YEAR	TOTAL CASES REPORTED	CASE INCIDENCE PER 100,000 POP.
July	1916	5728	154.5
August	1916	3143	85.0
August	1915	2883	78.0

**Measles.** There has been a marked decrease in the number of cases of measles reported during the month. This seems to be the usual phenomenon. During July, 1916, there were 2713 cases reported, while in the month just closed there were only 595. As compared with August, 1915, this disease was considerably more prevalent this year.

Comparative table follows:

MONTH	YEAR	TOTAL CASES REPORTED	CASE INCIDENCE PER 100,000 POP.
July	1916	2713	73.3
August	1916	595	16.1
August	1915	370	10.0

The following cities and towns have exceeded their endemic index for the month of August:

(Endemic index signifies the average for five years of reported cases exclusive of epidemics. This index is applied to each city and town for each month for every communicable disease.)

Amherst .....(1) 8	Malden .....(3) 13
Cambridge .....(6) 24	Newton .....(2) 15
Fitchburg .....(1) 34	North Adams .....(1) 60
Lowell .....(12) 57	Somerville ....(2) 15
Leominster ....(1) 15	

**Diphtheria.** Diphtheria showed a slight decrease during the month of August, as compared with the previous month, and a considerable decrease as compared with August, 1915. Ludlow has had a sharp outbreak of this disease during the month, while the number of cases reported from Fitchburg is well above the average. Comparative table follows:

MONTH	YEAR	TOTAL CASES REPORTED	CASE INCIDENCE PER 100,000 POP.
July	1916	495	13.4
August	1916	460	12.4
August	1915	564	15.3

The following cities and towns have exceeded their endemic index for diphtheria:

Fitchburg .....(5) 24	Reading .....(0) 10
Lawrence .....(3) 10	Watertown .....(1) 18
Lowell .....(7) 18	Westfield .....(0) 7
Ludlow .....(0) 26	

**Whooping Cough.** The number of cases of this disease reported during the month is smaller, both in comparison with August, 1915, and with July of this year. Comparative table follows:

Reading .....	1	Wareham .....	4
Revere .....	4	Whitman .....	1
Savoy .....	1	Webster .....	1
Salem .....	5	West Blyston .....	1
Southwick .....	1	Worcester .....	5
Springfield .....	17	Yarmouth .....	1
Somerville .....	8	Barre .....	1
Stoughton .....	3	Charlton .....	2
Southbridge .....	4	Launcester .....	1
Taunton .....	1	North Brookfield .....	1
Uxbridge .....	2	Leominster .....	1
West Springfield .....	1	Sturbridge .....	1
Westfield .....	3		

**Mortality.** There were 39 deaths reported to this Department from anterior poliomyelitis during August. This gives a fatality rate of 15.2%. While the returns of deaths upon which these figures are based are admittedly incomplete, it indicates that the infection is of an unusually virulent nature.

**Investigation.** The State District Health officers and the epidemiologist, working in co-operation with the local health authorities, are making a study of all reported cases. The detailed result of these studies will be published later in the year.

**Typhoid Fever.** During the closing days of August there was a sharp outbreak of typhoid fever reported from Lynn. The early results of the investigation show that the mode of transmission was undoubtedly milk. All of the cases occurred on a single milk route.

## Correspondence.

### "A SQUARE DEAL TO ALL."

LOWELL, MASS., September 5, 1916.

Mr. Editor: There has, for a long time, been a growing dissatisfaction with the application of the Workmen's Compensation Act. This dissatisfaction, at the annual meeting of the Middlesex North District Medical Society in April, 1916, seemed to come to such a climax that there arose a general demand for an investigation of the act in its relationship to the medical profession. Pursuant to this idea, there was appointed at this meeting a committee to investigate the status of the physicians under the act. This committee found that the act was passed by the Legislature of 1911. They also found that Section V, of Part II, which is as follows:

Part II, Section V. During the first two weeks after the injury, the Association shall furnish reasonable medical and hospital services, and medicine, when they are needed,

allowed the injured workman to select his own physician when he so desired. We mean by this not that the act specifically gave him his right, but rather that it did not specifically deny him the right.

The committee found further that this act was amended in 1914, in such a way as to preclude all possibility of free choice of physician on the part of the workman injured, except in case of grave emergency, and as to whether or not any situation in which the workman might find himself, represented an emergency, not he, but the Industrial Accident Board, sitting on the case probably months afterward, must decide. Section V, of Part II, of amended

act of 1914, again the section that relates to medical services, reads as follows:

Part II, Section V, is hereby amended by striking out Section V, of Part II., and inserting in place thereof the following new section:

Section V. During the first two weeks after the injury, and if the employee is not immediately incapacitated thereby from earning full wages, then from time of such incapacity, and in unusual cases, in the discretion of the Board, for a longer period, the Association shall furnish reasonable medical and hospital services and medicines when they are needed.

Where, in a case of emergency or other justifiable cause, a physician other than the one provided by the Association is called in to treat the injured employee, the reasonable cost of his services shall be paid by the Association subject to the approval of the Industrial Accident Board. Such approval shall be granted only if the Board finds that there was such justifiable cause and that the charge for the services is reasonable.

This committee concluded, first from a perusal of the original act of 1911 and the amended act of 1914, and also from an interpretation of the act as presented by Justice Carroll of the Massachusetts Supreme Court, that the Workmen's Compensation Act works to the unfair advantage of the medical profession.

A special meeting of the Middlesex North District Medical Society was called on June 14th, to hear the report of its special committee. The committee reported the situation as outlined above with recommendations which were as follows.

1st. That an endeavor be made to so amend the Workmen's Compensation Act as to give the injured workman the right to select his physician.

2d. That every District Medical Society in Massachusetts be invited to co-operate with the Middlesex North District in an endeavor to bring relief to this situation.

3d. That the Massachusetts Homeopathic Society be invited also to co-operate.

The original declaration as to the unfairness of the law and these recommendations were accepted unanimously and this committee was given full authority to carry on the work.

Immediately the committee got in touch with every district society in the state by means of the following letter which is self-explanatory:

Secretary of . . . . District Medical Society.

Dear Doctor: This committee was appointed at the annual meeting of the Middlesex North District Medical Society, to investigate the Workmen's Compensation Act in its relationship to the medical profession, because of the marked dissatisfaction with the Act as it now stands.

This committee found that the insurance companies have the sole right to name the attending physician and that the workman has no voice in the selection of the physician who is to attend him, provided that he wishes to receive all the benefits of the Act.

We made recommendations to our Society which were accepted and we were given full power to proceed with the work.

We are of the belief that relief from these unfair conditions is to have the Workmen's Compensation Act so amended, that the injured workman may select his physician without sacrificing any of the benefits of the Act.

It is suggested, in order to bring this about, that each district society appoint a like committee of five, and the large committee thus formed is to meet in Worcester, at Hotel Ram-

croft on Sept. 20, 1916, there to discuss freely the matter involved, and to formulate a plan of active campaign for the relief measure.

Will you, in furtherance of this object, let us send a representative to the next meeting of your district society that we may explain in more detail the plan of action we have in mind for the relief of this situation?

This committee will appreciate a reply at your earliest convenience, in enclosed stamped envelope, and would thank you to state the date, hour and place of your next meeting, which we understand is in July.

We are,

Very truly yours,

COMMITTEE ON WORKMEN'S  
COMPENSATION ACT.

*Middlesex North District Medical Society.*

It was a source of great gratification to the committee to note how widespread was the interest in this matter. The responses to this circular letter were enthusiastic and displayed an eagerness to co-operate. When a reply was received giving the date of the mid-summer meeting, the following letter was sent to each member of the district society:

*Dear Doctor:* Our request for a like committee from your district is to be considered at the next meeting of your district medical society.

#### THE CAUSE.

We address you personally with the hope that you are interested in the Workmen's Compensation Act to the extent that it shall be fair not only to the workman, but also to the insurance associations and to the medical profession. We feel that in its present state, it works to the unfair advantage of the physician and his patient.

#### THE EFFECT.

*First*—it diverts, in many instances, patients and even their families from the care of their physician.

*Second*—It forces patients who have every confidence in their regular physician to accept the services of another who may not be known to them, provided they wish to avail themselves of all the benefits of the Act.

There is no doubt that the service offered by the insurance associations is good, but it is positively no better than the workman himself could and would select.

We have no quarrel with the insurance companies, none whatever with the members of the medical fraternity who are doing the work, but we believe that any act which deprives John Smith, a human being, of his divine right to select his attendant when either accident or sickness befalls him, is grossly unfair—no matter who pays the bill.

#### THE REMEDY.

The remedy, it seems to us, is to have the Workmen's Compensation Act so amended that the injured workman may select his physician without sacrificing any of the benefits of the Act.

We ask you to attend the next meeting of your district medical society there to join in the discussions of this subject.

Our committee would be grateful if you could reply to this communication, but if you cannot, please attend the meeting as asked.

We are,

Yours very truly,

COMMITTEE ON WORKMEN'S  
COMPENSATION ACT.

*Middlesex North District Medical Society.*

All of the districts holding mid-summer meetings were visited by members of the committee, and the work explained in detail.

These men were universally well received, respectfully listened to, and on the instant it was apparent that they had struck a responsive chord. The plan as outlined to the various districts is as follows:

A convention will be held in Worcester, Sept. 20, 1916—this convention to be made up of representatives from every district medical society in the state and from the Massachusetts Homoeopathic Society; this convention to take up the work and carry it to its successful issue.

The various districts have thought so well of this plan that they practically all at this time have appointed representatives to sit in this convention.

The committee from Middlesex North District found that many of the cases coming under the Workmen's Compensation Act were being cared for in the charity wards of the various hospitals of the district, that is, a nominal sum was being paid the hospital for the board and nursing of these cases, but the staff physicians were receiving absolutely no recompense for their services.

This committee, at no angle from which they might view the situation, could see these cases in the light of charity cases, and consequently concluded that the men rendering the service were having their services commended under false pretenses.

The committee got in touch with the trustees and superintendents of the hospitals, pointed out to them the unfairness of the situation, which they quickly saw, and gladly gave the committee a written statement that henceforth these cases must be looked upon as the private cases of the physicians rendering the service. The consequence of this is that today in Lowell all physicians are being paid for all those hospital cases coming under the Workmen's Compensation Act.

We feel that the demands of the physicians of Massachusetts are so reasonable that they will meet with the same degree of success before the Massachusetts Legislature as we in Lowell met with in our dealings with the officials of our hospitals.

We are sure that all that is necessary to bring the desired change about is a united stand by the physicians throughout the state.

Respectfully yours,

M. A. TOWN, M.D., *Chairman*  
J. A. MEEHAN, M.D., *Secretary*

#### THE VIEWPOINTS

LAWRENCE, MASS., Sept. 22, 1916.

*Mr. Editor:* The closing sentence of an editorial discussing the relations of the physician to the Workmen's Compensation Act in the *JOURNAL* of Vol. 27, 1916, reads as follows:

"The court decision will leave the test of work independent physicians entitled to their ordinary similar services to employees, if once they have passed this sort of insurance."

If there is no doubt concerning the right of independent physicians to their ordinary services, this sentence means that the Workmen's Compensation Act of the Massachusetts Medical Society, members of the Society are not to be considered as people who are interested in the compensation of their services unless they are doctors who are not members of the Society. This is a very serious statement, and it is paid for the service of the physician.

In the editorial, it is stated that the Workmen's Compensation Act is a very serious statement, and it is paid for the service of the physician. It is a very serious statement, and it is paid for the service of the physician.

For the purpose of the Workmen's Compensation Act, it is a very serious statement, and it is paid for the service of the physician. It is a very serious statement, and it is paid for the service of the physician.

frères to refuse to treat patients of theirs because they might not be paid for their services. The failure to appreciate that injured employees and the doctor in the industrial centre can have the same intimate personal relation that the patient and doctor enjoy among the wealthy classes, is the reason this advice is offered. Injured employees receiving ten to twenty dollars a week are simply out-patient department material in Boston, but they are not that in poorer communities, and it is not possible for them to be so considered. The physician in wealthy medical centres can and does recoup for himself through charges to his wealthy patients remuneration for the hours spent in the out-patient. Such a system is workable where the percentage of patients in a community able to pay is sufficiently large, which it is not in industrial centres.

It is my impression that the supply of doctors is not now excessive, for it is necessary to consider the demands of the epidemic seasons. If this supply is to be maintained for the use of the general community, it is necessary that the remuneration be sufficiently large to attract competent men.

If it is thought or said that these employees of small income should not be expected to pay for medical attendance, I agree; but it must be remembered that the surgeon in the medical centre who gets five hundred dollars for operating on a stockholder or well paid official of an industrial plant, gets his fee from the same source as Dr. X who gets a small fee for treating the employee. In the first instance it has simply passed through the hands of one more person.

Yours very truly,

W. H. MERRILL, M.D.

#### PYORRHEA ALVEOLARIS AND ITS TREATMENT

WESTPORT-ON-LAKE-CHAMPLAIN, N. Y., Sept. 14, 1916.

MR. Editor: In view of your editorial in your issue of September 14, 1916, I would direct your attention to an article by me on this subject in the August number of *American Medicine*. In it, I state that I have found Dr. Augustus B. Wadsworth's mouth wash of very great value when other methods of treatment have notably failed. I believe you will render service to many sufferers from the disease, by directing attention of physicians to my article and to the statement referred to.

BEVERLEY ROBINSON, M.D.

#### NOTICE.

THE HENRY S. WELLCOME PRIZES, OFFERED THROUGH THE ASSOCIATION OF MILITARY SURGEONS, viz: First prize, a gold medal and \$300.00; second prize, a silver medal and \$200.00. Open for competition to all present and former Medical Officers of the Army, Navy, Public Health Service, Organized Militia, U. S. Vols., Medical Reserve Corps of the Army, Navy and of the officers Reserve Corps of the U. S. Army, will not be awarded until after December 15, 1916, the Council of the Association having voted to extend the time of entry of competing essays to that date, because so large a number of the members are now with the troops on the Border.

Several essays have already been received and a large additional number are expected to be entered for such honorable and valuable prizes. The subject for the first prize is "The most practicable plan for the organization, training and utilization of the Medical Officers of the Medical Reserve Corps, U. S. Army and Navy and of the Medical Officers of the Officers Reserve Corps, U. S. Army, in peace and war."

That of the second prize is: "The influence of the

European War on the transmission of the infections of diseases, with special reference to its effect upon disease conditions of the United States."

Essays (5 copies signed by *nom de plume*) not to exceed 20,000 words, exclusive of tables, must be addressed to the Secretary of the Association of Military Surgeons, U. S. Army Medical Museum, Washington, D. C.

#### SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The members of the Society have been cordially invited by the Boston district of the Massachusetts Homeopathic Medical Society to attend a meeting of that Society on Thursday evening, October 5, at 8 o'clock, at the Evans Memorial Building, East Concord Street, Boston.

Dr. McLaughlin, Commissioner of Health, will speak on Anterior Polymyositis. It is hoped that many members of the Suffolk District Medical Society will be able to accept this invitation.

DAVID CHEEVER, Secretary,  
Suffolk District Medical Society.

#### APPOINTMENT.

DR. L. D. BRISTOL, Professor of Bacteriology and Hygiene, and Director of the State Public Health Laboratories at the University of North Dakota, has accepted the newly created Boston Dispensary Fellowship in Public Health in the Department of Preventive Medicine at the Harvard Medical School, Boston.

#### RECENT DEATHS.

DR. SANFORD HANSCOM died at his home in Somerville, September 20, aged 75 years. He was born in Albion, Me., January 28, 1841, and was educated at Colby College and at the Harvard Medical School from which he graduated in the class of 1868, previously having served in the Civil War. Dr. Hanscom was a member of the Somerville school board for 17 years and was a trustee of the public library. He was a member of the American Medical Association, of the Massachusetts Medical Society, of the Loyal Legion, and of the Royal Arcanum. He is survived by a widow and a daughter.

DR. WYLLIS GILBERT EATON died at his home in Lowell, June 26, 1916, aged 62 years, of coronary sclerosis. He was born in Lawrence, February 23, 1854, was a graduate of Dartmouth College in the class of 1875, and of the Harvard Medical School in 1879, settling in Lowell and joining the Massachusetts Medical Society in that year. He was visiting physician to the Lowell Hospital, and until May, 1916, was Councilor and Supervising Censor of the Middlesex North District Medical Society, of which he had previously been secretary and president.

DR. JOHN JOSEPH THOMPSON died at his home in Webster as a result of cerebral hemorrhage, September 16, aged 56 years. He was born in Webster, attended Nichols Academy in Dudley, graduated from Holy Cross College, Worcester, in 1882 and from Jefferson Medical College, Philadelphia, in 1887. He was town physician for 15 years and was chairman of the school committee for 10 years, one of the recently built schoolhouses of the town having been named for him. He was a member of the following societies: American Medical Association, Massachusetts Medical Society, Connecticut State Medical Society, Webster Council of Knights of Columbus, Ben Franklin Council Royal Arcanum. He is survived by a sister.

## 12

October 5, 1916

more than a student; he is an indefatigable worker, a seeker after knowledge for its own sake,—knowledge in advance of others and also knowledge of what men have known before him. There must also be a certain bookish flavor about him before we can call him a scholar. He must be a student of his profession and he must love its literature. We can hardly conceive such a man who does not also love the literature of all the ages. He loves books and treasures them. He appreciates Cicero's tribute to liberal studies in his plea for the poet Archias: "For other occupations are not suited to every time, or to every age or place; but these studies are the food of youth, the delight of old age, the ornament of prosperity, the refuge and comfort of adversity; a delight at home and no hindrance abroad; they are companions by night and in travel and in the country."

Scholarship is unselfish, seeks knowledge for its own sake and takes pleasure in imparting it; it seeks to make experience profitable. A medical scholar makes the bitter experience of disease and death conduce to the good of future days, for the human body is his most treasured book, with all its wondrous revelations.

Doubtless there are medical scholars who are recluses, who are content to pore over the records of the past, who know the physicians of the older days better than those of the present. Perhaps to many, the title of medical scholar would attach to them alone, but they deserve to be classed as misers who are content with the accumulation of literary riches. To me, the medical scholar is more likely to be also a man of action than the scholar in any other branch of learning. With so loose and liberal a definition, it is not easy to distinguish between the practitioner and the experimenter, the research student and the scholar; nor is it necessary for the present purpose.

The learning of medical scholars, as shown in their writings, reflects the spirit and the frailties of the age in which they lived. Their character varies with the advance of learning. Sometimes they discuss secular or religious, sometimes special medical topics, often they blend the three. Perhaps they are at their best when they record the things that have occurred under their observation, preserving for us the history of epidemics and prevailing diseases, or even the story of a single life.

The patron saint and godfather of so many hospitals, Saint Luke, we may look upon as the earliest medical scholar of the Christian Era. He is known to us better as a sacred historian than as a physician, but it is his narrative of our Lord's life which has preserved the stories of the healing of the sick and the raising of the dead, and the story of the good Samaritan who succored the wounded man while others passed by on the other side, and whose use of oil and

wine foreshadowed the present use of alcohol as a surgical dressing.

However one may regard those miraculous events, the narratives show the interest of the writer in the sick and the suffering, very much as a physician of the present day, writing a history which involved questions of life and death, health and disease, would be likely to dwell a little more fully than a non-medical historian, upon those matters.

It would be an endless task to trace the medical scholar from that day to our own, but coming down to a nearer period and confining our attention to men of English birth, one can scarcely avoid the mention of Sir Thomas Browne. His *Religio Medici* is an object of study for students of general literature and his urn burial has especially interested the advocates of cremation. One of his books was entitled *Pseudodoxia Epidemica*, or a Treatise on Vulgar and Common Errors, in which he rebuked the superstitions of the day; but he, himself, shared the current belief in witchcraft and gave testimony at a trial of two unfortunate, alleged witches which probably tended to their conviction.

Dr. John Halle has left us a poem more simple and direct in its diction than the writings of Sir Thomas Browne, but its value today is as great as in the sixteenth century when he wrote it.

"When thou arte calide at anye time  
A patient to seee  
And doste perceave the cure to greate  
And ponderous for thee

See that thou laye disdeyne aside  
And pride of thyne owne skyle  
And think no shame counsell to take  
But rather wyth good wyle

Gette one or two of experie men  
To helpe thee in that nede  
And make them partakers wyth thee  
In that worke to procede.

But one thing note when two or more  
Together joyned be  
Aboute the paynfull patient  
See that ye doe agree.

For naughte can more discomforte him  
That lies in griefe and payne  
Than heare that one of you dothe beare  
To other such disdeine.

Wherefore what so ye have to saye  
In things about your arte  
Let it be done among yourselves  
In secrete and aparte.

With one consent uniformlye  
Comforte the wounded man  
But unto some good friend of hys  
Express alle that ye can

See thou dispraise none other man  
His error tho' thou knowe  
For sure another for thy plague  
Shall thee like curtyse showe."

fore, formed in cold climates *because* the cold air is denser than warm air, and a greater amount of oxygen per unit of volume comes in contact with the surface of the lung.

But Lavoisier's writings contain also the germ of the truth.

In his communications of 1789, he states that, in spite of what should be expected, experiments with guinea pigs demonstrate that these animals take up the same amount of oxygen, and give off the same amount of carbon dioxide, whether they breathe pure oxygen or a mixture of oxygen and nitrogen. Lavoisier was already, therefore, on the right track. By 1789, he had overcome the technical difficulties of constructing apparatus for carrying out metabolism studies even in man; by 1791, one of his pupils, Seguin, had developed a method of measuring the amount of oxygen in a mixture of gases (measuring how much of the gas would combine with phosphorus<sup>20</sup>); and another pupil, Hassenfratz, by showing that the temperature in the lungs is no higher than elsewhere in the body, had corrected the erroneous notion that the oxidation takes place in the lungs. It is highly probable, therefore, that Lavoisier might soon have carried out experiments that would have anticipated a century of errors. But scientific work was interrupted by the French Revolution, and Lavoisier himself was executed early in 1794.

From the death of Lavoisier until 1866 there was but little change in views held by physiologists regarding oxidation. Certain investigators,—Regnault and Reiset<sup>21</sup> (1849), Müller<sup>22</sup> (1858),—as a result of experiments similar to those of Lavoisier, pointed out that the activity of the metabolism remains unaffected by the oxygen tension. But these experiments made little impression at the time.

Reform came from another quarter. Almost inextricably involved with the incorrect notion regarding the cause of oxidation was an incorrect idea concerning the place of oxidation. Oxidation was believed to take place, not in the tissues, but in the blood-stream. It was the gradual accumulation of data not in harmony with this latter belief, and indicating that oxidation takes place in the tissues, that led to a readjustment of the views regarding the cause of oxidation.

It is difficult to determine precisely who should be given credit for teaching us the truth regarding this matter. The question of the cause of oxidation and that of the place of oxidation—though two separate questions—are not clearly separated in the early discussions. The question arises not only: Who first taught the

truth as a matter of belief, but also: Who first experimentally established the facts upon which the truth could be based? The echoes of the fierce polemics of the '70's over these questions have not yet died out.

In 1838, Müller stated clearly<sup>23</sup> that oxidation does not take place in the blood, but in the tissues; he believed, however, that the respiration is not the result, but the cause, of the oxidation. In 1844, Vierordt stated correctly the facts of internal respiration<sup>24</sup>; that oxidation takes place in the tissues; and that the blood transports oxygen to the tissues, and takes carbon dioxide away from the tissues. Experimental confirmation of these hypotheses was furnished by L. Meyer in 1857<sup>25</sup>; Meyer demonstrated that the blood transports both carbon dioxide and oxygen.\* A further confirmation of this theory was furnished in 1863<sup>26</sup> when Panum showed that the amount of oxygen absorbed by dogs and the amount of carbon dioxide given off is not affected by the great loss of transporting power for oxygen which results from severe hemorrhage. In the subsequent polemics, these writers are given little credit; Pfliiger, indeed, in 1868 rejected Meyer's conclusions.<sup>27</sup>

Voit was probably the first<sup>28</sup> 1866 to incline physiologists to the belief that respiration is not the cause of metabolism, but the result of the needs of the metabolism. He pointed out that the carbon dioxide eliminated is independent of the ventilation of the lungs.<sup>29</sup> In 1868 he showed that neither by section of the vagus, formation of a pneumothorax or by hemorrhage, whereby respiration is diminished, can the amount of oxygen taken up or the amount of carbon dioxide given off be influenced.<sup>30</sup> In 1869 he showed that in leukemia a disease which was believed to be associated with diminished internal respiration<sup>31</sup> neither the oxygen intake nor the carbon dioxide output is affected. In the same year, Senator searched in vain for evidence of incomplete oxidation in dogs, cats, and rabbits after binding the thorax tightly.<sup>32</sup> In 1870 and 1871, Voit<sup>33</sup> discussed the whole subject at great length and answered especially the objections of Liebig who was teaching the old view.

Hoppe-Seyler accepted the new theory at least from the beginning, but did not furnish any experimental proof was complete until 1878.<sup>34</sup>

At first 1866-1868, Pflüger, who was then working on the gasometry of blood, strenuously opposed the new view.<sup>35</sup> In 1868 he stated: "No one will deny that in the blood that oxygen is continuously used up in the blood vessels," and described experimentally the "con-

<sup>20</sup> In 1780 Lavoisier demonstrated this apparatus to the members of the Academy, and in his communication described the main features of it; he promised to publish later a detailed description. In 1790 he again promised to describe this apparatus. I have searched for this promised report in probable places but have never been able to find it.

<sup>21</sup> The memoirs of the French Academy for 1790 were not published until 1797. A note of strong warning was issued in 1820, in that year. The intervening years are not mentioned. The Academy was suppressed in 1793.

and similar ones by Schmidt in Ludwig's laboratory, intended to demonstrate the presence in the blood, during suffocation, of products of incomplete oxidation. He declared, also, that dyspnea is due to products of incomplete oxidation.<sup>40</sup>

But Pflüger soon changed his opinion; he disproved his earlier findings of products of incomplete combustion in the blood, and, in 1872, rejected the old hypothesis,<sup>41</sup> going even so far as to assert that he had recognized and taught the correct theory even before Voit. In extra large type on page 46 of this paper occurs the following very important sentence which expresses the views of physiologists today: "Here lies (in the cell itself alone) the essential secret of the regulation of the oxygen used by the body; it is not determined by the blood pressure, the velocity of the blood stream, the activity of the heart, or the activity of the respiration."<sup>42</sup>

In 1875, both Voit<sup>43</sup> and Pflüger<sup>42</sup> complain that the new view is not everywhere known and accepted; according to Voit, even Liebig still opposed it. But that the results are not everywhere ignored is shown by Voit's further complaint against those who say that they recognized and demonstrated the truth before he (Voit) did; he disputes especially Pflüger's priority claims.

During the years 1875 to 1878 a great many papers on respiration and metabolism appeared from Pflüger's laboratory.<sup>43</sup> Many of them are very long and offer as evidence not only experiments carried out in Pflüger's laboratory, but an enormous amount of other evidence from all departments of biology. His own experiments deal largely with measurements of the amount of metabolism under conditions of varying oxygen supply. The papers are polemic in character and their influence on other physiologists is reflected in the gradual change in the nature of discussion. The earlier papers are devoted to demonstrating that the opponents of the new view are wrong. Pflüger opposed<sup>44</sup> especially the contentions of Ludwig and his pupils<sup>45</sup> that oxidation in the muscles is proportional to the velocity of the blood, and that during suffocation the blood contains products of incomplete oxidation. He seems to have overcome opposition to the new view toward the end of this period, for later papers<sup>46</sup> are directed largely at those—in Hoppe-Seyler's laboratory especially<sup>47</sup>—who dispute his claims for priority. Physiologists commonly give Pflüger credit for first demonstrating the truth regarding oxidation. As a matter of fact, Voit first taught the truth; but Pflüger overcame opposition and convinced the scientific world.

With the opening of his new institute in 1878 Pflüger seems to have concluded his work on respiration and turned his attention to other problems. Judging by a statement from Hoppe-Seyler's laboratory at this time,<sup>47</sup> the new view seems to have gained general acceptance. Lud-

wig alone holding out; Ludwig apparently never accepted the new view.<sup>48</sup> (He died in 1895.)

But since 1878—long enough ago it would seem for the facts to have filtered into clinical medicine—no physiologist has contended that products of incomplete oxidation will result from either poor respiration or poor circulation. It is to be hoped that more active emphasis on the practical aspect of physiology will purge clinical medicine of ideas generally recognized by physiologists as incorrect.

## INSUFFICIENT OXYGEN SUPPLY AS A FACTOR IN DISEASE.

BY FRANCIS H. MCCRUDDEN, S.B., M.D., BOSTON.

*Laboratory Director, Robert B. Brigham Hospital, Boston,**Assistant Professor of Applied Therapeutics, Tufts Medical School, Boston.*

IN the training of physicians more emphasis should be laid on the practical aspects of physiology.<sup>1</sup>

The best evidences that the medical student does not receive adequate instruction in the practical aspects of this important subject are the primitive notions of physiology so frequently exhibited in the explanations of the mechanism of disease and the mode of action of different forms of treatment, given in our clinical journals. The abundance of such evidences sometimes suggests that the steady advance of physiology makes but little impression on practical medicine.

No better example of the failure of a fundamental physiological fact to impress itself on clinical medicine can be cited than the constant recurrence of the myth of "insufficient oxygen supply," for over a century a favorite explanation of pathological symptoms. The belief in "insufficient oxygen supply" is based on an erroneous notion of the nature of metabolism, according to which the amount of oxidation is regulated by the respiration. The metabolic processes are sometimes compared with the blacksmith's fire, the lungs with the bellows; the intensity of the metabolism being attributed to the activity of the respiration.<sup>2</sup>

This notion is widespread. In the daily press it is reflected in the references to the relation between "correct breathing" and the "laws of health." It shows itself in the popular fallacy that in cold weather deep breathing is advisable because "deep breathing stimulates the metabolism and thereby develops heat."

But it is not confined to the laity. "The condition is due to products of insufficient oxygen supply" appears perennially in the clinical journals. Even in recent numbers of our leading clinical journals the dyspnea of heart disease is ascribed to products of incomplete oxidation,<sup>3</sup> and twice recently the notion has received favorable editorial comment in the *Journal of the American Medical Association*.<sup>4</sup> To cite one of the several similar passages in these papers:<sup>5</sup> "In the pure cardiac cases the dyspnea seems to depend on a slow or insufficient circulation, which results in a poor oxygenation of the tissues and may even cause a transient acidosis owing to the incomplete combustion of metabolic products."\*

\* Probably does not claim originality for this notion; he attributes it to Porces, Leimbörger and Markovici,<sup>6</sup> to Beddard and

One of the best known examples of this notion is the belief that gout and the "uric acid diathesis" are due to the accumulation of products—chiefly uric acid—of incomplete oxidation of protein.<sup>11</sup> This belief is one of the errors at the basis of the widely accepted hypotheses of Haig<sup>12</sup> concerning gout and many other diseases.

Liebig declares<sup>13</sup> that when people who suffer from uric acid concretions go to the country, they sometimes get, as a result of better oxygenation, concretions of oxalic acid—an oxidation product of uric acid; and that when they exercise and so absorb still more oxygen, the concretions are completely oxidized to carbon dioxide and water. Animals that drink much water, according to Liebig, excrete less uric acid than others; the water keeps the sparingly soluble uric acid in solution so that it becomes more completely oxidized to urea.

Many investigators have attributed symptoms in leukemia, chlorosis, and emphysema to the products of incomplete oxidation, believing that the symptoms result from decreased external or internal respiration respectively.<sup>13</sup>

The introduction of hypophosphites into medicine was due to the belief that phthisis is due to incomplete oxidation.<sup>14</sup> Phosphorus and its partly oxidized derivatives, the hypophosphites, were recommended in this disease in the belief that they attract oxygen to the tissues.

Nencki and Sieber<sup>15</sup> proposed to measure the oxidizing power of the body under different conditions by determining the amount of benzol that can be oxidized to phenol; and concluded, as a result of such experiments, that in leukemia there is a decreased power of oxidation, in anemia and chlorosis no change.

Examples might be multiplied<sup>16</sup>; but these few will suffice to illustrate the nature of the fallacy.

The source of the error is found in the writings of Lavoisier.

In 1777,<sup>17</sup> Lavoisier cited metabolism experiments which he had carried out on birds, to show that respiration results in a combination of the carbon of the blood with oxygen to form carbon dioxide; he concluded that the process is analogous to that which two years previously he had described as combustion. But in elaborating this theory twelve years later,<sup>18</sup> he laid the foundation of future error. He speaks of incomplete oxidation of digestive products as a possible cause of disease, and urges the use of purgatives to rid the body of such products; he attributes the fevers of hospitals and prisons to the insufficient oxidation resulting from the impure air. In the following year<sup>19</sup> he declared that the metabolism is more active, and more heat, there-

Pembrey,<sup>7</sup> and to Lewis and Ranroft.<sup>8</sup> And he thereby illustrates the manner in which a false notion—like a rumor—spreads, each repetition of the notion, as it becomes further removed from the facts, becoming more incorrect and yet more dogmatic. These authors carefully avoided stating any such hypothesis as Peabody attributes to them; Beddard and Pembrey, in fact, state that the evidence is against such a hypothesis.

The hypothesis was, however, proposed by Pfleger in 1868.<sup>9</sup> Later, however (1872),<sup>10</sup> it was rejected and vigorously combated by him. But Peabody does not refer to this.

striction of carbohydrates and proteins, subsequent to a day or two of fasting, he kept the animals sugar-free indefinitely, though they lost some weight, retaining, however, both strength and activity.

In more severe induced cases, where the fast was prolonged to a week or more, and the diet greatly reduced for the purpose of depressing metabolism, return to increase in weight and metabolism were accompanied by a recurrence of sugar; persistence of sugar tolerance reduced carbohydrate tolerance, and repeated fasting periods increased it. Prevention of glycosuria reduces the weight for a period, and abolishes ketonuria; later, on a similar diet, weight increases without acidosis and without injury to the islands of Langerhans. Absence of urinary sugar ketones and of hyperglycemia increases tolerance for carbohydrates and protects internal secretion of ductless glands, especially of the pancreas and of the pars intermedia of the hypophysis and probably decrease of kidney permeability.

Stillman, in an illuminating paper very recently published, has further analyzed glycosurias with reference to that most dangerous complication, acidosis. Modern treatment has attempted control of acidosis on the discarded theory of von Noorden, that "fats burn in the fuel of carbohydrates." As Stillman has noted, rational treatment of glycosuria has been retarded by the accepted idea, that "over-feeding with fat is harmless, and even beneficial, and that carbohydrate feeding is required to avert threatening coma."

Excess of fat frequently predisposes to acidosis as shown in a case under my care during the present season, whose diet on February 16th consisted of protein, 239 calories; fat, 1388 calories; carbohydrate, 237 calories, with sugar output of 80.5 grams in 24 hours, and urinary ammonia, 1,696, more than five times the normal. On the following day the protein was reduced from 239 to 98 calories; the fat from 1388 to 200 calories, and the carbohydrate from 237 to 142 calories, the greatest relative reduction being in fats. The result on the fifth day of this reduction was a fall of sugar to zero and of ammonia to normal, after which protein and carbohydrate were gradually increased, with fats to about one-half the original quantity, without development of sugar or increase of ammonia above normal.

Stettin's success with cases incipiently surgical, in preventing advanced complications leading towards amputations, was due first, to exact and skillful medical direction, and second to the most painstaking surgical care. It is a duty to call a competent surgeon at the very first sign of infection of any sort, especially of the lower extremities. Joslin notes that diabetics live for years on an atrocious diet, untreated, without developing coma, until they are advised by some inexperienced medico, greatly to increase the fats or decrease carbohydrates, when coma promptly supervenes. Acidosis is not a product

of carbohydrates, but develops from fats and protein, sudden change of which above or below the customary amount, often in these long standing cases, acts like poison. Patients tending toward acidosis should at first be deprived of fats, and its introduction to the diet be made very gradually. Since, though a valuable food, it cannot be metabolized until the system becomes adjusted to its use. Prior to fasting, in such cases, Joslin wisely advised the *not common* plan of eliminating fat for some days from the dietary; then cutting out proteins, a factor of somewhat lesser moment for development of acidosis, but quite important enough. Reduce now quickly carbohydrates, halving each day, for three days, and proceed to hunger days with graduated return to prescribed diet. Infectious cases, while fasting, should not be deprived of sodium chloride and should have abundant water, and if there be a tendency toward coma and vomiting, normal saline solution, per colon, should be constantly introduced by the Murphy method or by hypodermolysis of salt solution. Small rather than large amounts of sodium bicarbonate are most efficient, half an ounce or less in 24 hours being usually sufficient; frequently *none* is required in the treatment of acidosis. Intravenous injection has been discarded.

Control of sugar, important as it is, becomes subordinate to the *control of acidosis*, which is associated with decreased blood alkalinity to the point of subnormal. Accumulation of hemic acids, as pointed out by Stillman, neutralizes a portion of the normal sodium bicarbonate of the blood and, when advanced in an exaggerated degree, produces death. *Reduced excretion of acids, or excessive production* is equally destructive of tolerance. Fruits, as noted by many physiologists, notably Bunge and by Sherman, increase hemic alkalinity by the introduction of easily assailable alkaline bases.

Acidosis may be determined by urinalysis when excretion is not impaired, but increased production requires more elaborate tests. For determining over-production, for faulty elimination due to decreased kidney permeability, the direct method of Van Slyke, from the blood admits of estimation of acid retention, as compared with urinary excretion, and adds valuable data for prognosis and treatment, as also does the use of Haldane's apparatus, both, however, requiring considerable training for exactness.

Stillman divides fasting glycosurias as regards acidosis, into four groups, and shows that the same individual may react at different fasting periods, in an entirely different manner.

Group 1 represents cases with normal hemic bicarbonate retention (euglycemia), no acidosis, these being a good percentage of all cases.

2. Cases which under fast, or recover from acid intoxication, even showed at the verge of coma, which are less frequent to observe.

3. Those cases showing only a moderately

by persistently diminished bicarbonate reserve in the blood, and increased ammonia secretion.

4. Such rare cases as develop acidosis while fasting, though previously free.

Sydenham and Rollo many years ago demonstrated that diabetics are made sugar-free by an exclusively flesh diet, and, until Mosse determined that a wholly meat and fat diet induced coma, such continued to be the approved treatment. Bouchard, studying auto-intoxication, showed that the feces of meat-fed animals were intensely toxic, as compared with vegetable eaters; as also did Herter. The bacteria of meat are putrefactive in type; proteolytic organisms, producing ptomaines and toxæmia. Putrefactive changes in the colon, of the residue of flesh, tend to irritation of the colon mucosa or to ulceration, and to *non-resistance* of the colon membrane to the absorption of toxins.

Falta states that "much meat is injurious to diabetics," animal protein having a higher percentage of *purin bodies* than vegetable protein, and this observation is confirmed by Allen. Falta says that some glycosuria patients are more sensitive to protein than to carbohydrates.

Graham Lusk, in a paper read before the New York Academy of Medicine within the month, gives as his opinion, as the result of observation and experimental work, that 4 or 5 grams of nitrogen, *i.e.*, 25 to 30 grams of protein in 24 hours, is sufficient for body needs in health, for the average weight adult and *practically all* that will be appropriated.

Von Noorden recognizes that a period of restricted diet, such as green vegetable days, raises the tolerance for carbohydrates "provided no meat be given with them."

Klemperer, in cases of acidosis, advises vegetable days, followed by carbohydrates, with butter and eggs "but no meat whatever." He says "meat spoils the results; even eggs may do so; vegetable albumen is well borne." The albumen of eggs in a small proportion of subjects, in any condition of health, produces a condition simulating anaphylaxis.

Naunyn finds the benefits of "hunger days," or vegetable days, are dependent upon the exclusion of meat, and says "the general benefit attaching to all 'grain cures' is the exclusion of . . . harmful foods such as meat."

In Allen's judgment much of the benefit of the *oat diet* is due to the complete withdrawal of meat, in which conclusion Chittenden, Combe, Folin, Fisher and many others agree.

Physiologists demonstrate that the function of protein is to replace wear of living tissues; that of carbohydrates, by their combustion, to maintain heat and muscular activity. As Kellogg aptly says, "Carbohydrate is the coal, while protein is the metal repair for the machinery."

I have, however, observed a patient for four months, who had been meat-free for two years, with unusually increased tolerance for carbohydrates, and reduction of sugar output to zero, who experiment-

ally ate for one month, along with vegetable protein, 250 calories daily of chicken and bacon, without return of glycosuria or acidosis, although the case had been one of a most obstinate character. In this exceptional instance, appetite was lost for exclusively vegetable foods, and regained only by the addition of a modest amount of flesh diet. This case illustrates well, effects of nervous strain upon the delicately poised glycosuria, as a week in New York, required by illness in her family, and consequent emotional stress, without change of diet—returned with sugar, from a daily output of zero, when patient left the institution, to 46½ grams; ammonia increased from normal to great excess; on return, under normal mental conditions, in three days sugar was down to 6 grams, ammonia normal. One must recognize, that in this case mentioned, tolerance had been established and health restored by low fats and moderate proteins, by regular "hunger days" followed on each occasion by two "green days" and slow return to moderate carbohydrate content. The sound maxim of Virgil, "*in medio tutissimus ibis*," requires much caution and judgment in application to determine what is the middle course in which you will go safest, since that which is the middle course at one stage of any case, may be an extreme course at another. As in all other treatment of disease, hard and fast rules fail in diabetes, since one must in reason consider, not only the chemistry of the patient, but also the human element of psychological coöperation and physical appetite.

Benedict and Joslin have independently proved that the most advanced cases of diabetes retain some degree of power to burn carbohydrates. Joslin had no death in a mixed group of diabetics in 350 days, under more or less prolonged intermittent fasting treatment, and has found among 912 cases, in which the immediate causes of death have been varied, 64% were associated with coma; he states that coma can nearly always be foreseen and prevented by watching for acidosis, since the basic disease, diabetes, is chronic in character, and offers ample warnings to that medical attendant, who is observant and wary. Ether anesthesia would wisely be avoided; especially is the danger of coma increased in persons past fifty years of age, on account of impairment of kidney elimination; *general or acute local infections* often add the final factor, precipitating coma. Speaking of infections of the legs, such as slowly advancing gangrene, Joslin deprecates delay in active treatment and says: "handicapped by a lingering infection, which only too often is allowed to continue for months, with kidneys less efficient for throwing off the acidosis attack; deprived of exercise—that recently proven stimulus to sugar consumption—these pitiful cases frequently meet a fourth enemy in ether anesthesia; and is it any wonder that a formerly innocent disease becomes virulent, and the victim dies of coma?"

Attention has recently been called, in persons developing coma, to a new sign, *i.e.*, the rapid decrease of intraocular tension, this lowered eye

John Arbuthnot, M.D., of Aberdeen, was the companion of Pope, Gay, Swift and Parnell and reflected honor on our profession. In 1704, he published "An Argument for Divine Providence Drawn from the Equal Number of Births of Both Sexes," which procured his admission to the Royal Society. How shocked he would be today if he could know that there were in Germany over 780,000 surplus women, and in Austria 600,000, before the outbreak of the present war, and that a similar inequality exists in other nations. It is fortunate that the existence of Divine Providence does not depend upon an argument based upon such premises.

Dr. John Hall, of Shakespeare's time, is a name which stimulates our imagination and curiosity. He was respected in Stratford, where he lived, and married Shakespeare's daughter, Susanna. Did Shakespeare discuss with his son-in-law the various medical matters in his own plays which have excited so much comment in later days? It is a disappointment to find that Black, in his story of Judith Shakespeare, has so little to say about her medical brother-in-law.

Dr. John Brown of Edinburgh lived within the remembrance of some of us, and all of us know his "Rab and his Friends"—a story of appreciation of an animal friend, but also a description of the medical students of Edinburgh of his day. It was of them that he made the distinction between pity as an emotion and pity as a motive. In his somewhat boisterous students, pity as an emotion leading to tears and useless exclamations was dead, but as a motive inciting to help, it was alive and active.

America has been fruitful in medical scholars. Time fails us to speak of Rush and Jacob Bigelow and his son Henry, of Bowditch and Jackson, and the host whose names crowd upon us. We think of Holmes and Weir Mitchell, both of whom contributed alike to medical and general literature. One may feel that a medical education furnishes an admirable foundation for a literary career.

A monograph by Dr. Henry I. Bowditch on Diaphragmatic Hernia, deserves especial mention, as it illustrates scholarly work at the bedside, in the autopsy room, the library and the study. It was he who gave some of the oldest of us our first lessons in the use of the stethoscope. Going about the wards of the Massachusetts General Hospital with a class of students to study healthy lung and heart sounds he came upon a young man with an injury, probably a fracture of the spine. Listening for the heart sounds, he found the heart dislocated to the right and only the sounds of intestinal gurgles in the left chest. He made the diagnosis of rupture of the diaphragm. When the patient died, a few days later, an autopsy was refused. Dr. Bowditch entered the autopsy room late at night and by the light of the moon made an examination which disclosed not a

rupture, but almost complete congenital absence of the left side of the diaphragm. Of this case, he wrote for his Harvard Class Book:

"The case interested me very deeply, and I looked in books and journals, American and foreign, for others similar. Between 1610 and 1846, I could find only eighty-eight cases. These I tabulated according to the 'Numerical Method' of my dear master Louis, and tried to extract from them all the truths they contained, anatomical, symptomatic, and causes; with diagnosis and prognosis as to the duration of life and treatment. I had a most delightful work, away from all the cares of common and professional life. I knew I was doing what had not been done before, and I knew that I must necessarily make a compact expression of the truth on the subject which would be worthy of respect and useful to any physician who should meet such a case. In my preface to the pamphlet (p. 77) that I printed from the *Journal*, I closed with these words, 'I hope that the memoir will be useful to the future student of Diaphragmatic Hernia, but the examination of it can never afford anyone a tithe of the pleasure or profit the original preparation of it afforded me.'"

As one of the foremost of American scholars must be mentioned John Billings. Graduated from a small medical college in the West, he served with distinction as a military surgeon during the Civil War and at its close was attached to Medical Headquarters at Washington. There, he was instrumental in building up the Library of the Surgeon General's Office until it ranks with the great libraries of Paris and London. He was the inspirer and first editor of the *Index Catalogue*, which is, practically, a catalogue of all medical books and an index to all medical journals, and, after retiring from the army by reason of years, he became the librarian of the New York Library. All medical scholars who have occasion to learn what their predecessors have done are indebted to the scholarship and industry of Dr. Billings. And I am sure we may incoincidentally find friend and successor, Dr. Robert Fletcher and the Librarian of our Boston Medical Library, Dr. James R. Chadwick, for our M.D. and Librarian has greatly encouraged scholarship.

It was scholarly work too, the collection of the scattered records of our Civil War, and the combining them in those volumes, the *Records of the War*, which form a part of the *Records of the Nation*. One can read later of their use in the preparation of our medical history, and how the records were capable of more than one use, and may there learn to appreciate the value of the thing of which they were made. It is a tribute to our present generation that we have preserved the records of our Civil War, and some extent of our medical history.

It is a tribute to our present generation

lowed these scholars of the past. The names that have survived the longest are those of the men who have studied most closely the human body, which I have already designated as the medical student's most precious volume. Our anatomical and clinical vocabularies have perpetuated the names of these scholars more carefully than any hall of fame. It is the recorders of facts rather than opinions who have lived. The more we learn of these learned physicians dead and gone, the greater our reverence. They had their jealousies, their human frailties, but they were leaders of thought and they sought the good of the human race. Their names may perish, their books may become obsolete, but no man works as a true scholar, seeking knowledge for its own sake, and sharing it with his friends and his students, without leaving the world a little better for his labors. Their unrecognized influence lives about us still.

There is work for the present-day scholar. It must be a medical scholar who will deduce the lessons to be gathered from the fearful carnage of the present European war, even as the scholars of our Civil War gathered the lessons of those fateful years, so that all the wounds and human waste of this time of frightfulness shall not be entirely in vain.

Even the present athletic furor is not without its lessons for the medical scholar who tabulates the heart strain and measures and records the body waste. Never was a wider field open to the medical student.

One duty of the medical scholar of today will be to present to the intelligent public an honest view of life and disease, that the strange doctrines which flourish among us may cease to attract otherwise intelligent individuals.

Possibly scholars themselves need caution lest in rebuking the errors of others, the "pseudodoxia epidemica" of the present day, they themselves shall merit the criticism of some individual who may speak to the John Harvard scholars of some future year.

In giving these John Harvard scholarships, the University grants no empty honor, for they carry with them not only their high academic distinction, but also a responsibility. There devolves upon these John Harvard scholars the duty that, so far as in them lies, they shall maintain for their chosen profession its rank as a scholarly and beneficent profession—a profession whose object is not alone the diminution of suffering, but the increase of knowledge and the improvement of the human race.

## Therapeutic and Preventive Medicine.

### TREATMENT OF DIABETES.\*

By F. FREMONT-SMITH, A.B., M.D.,  
WASHINGTON, D.C.,

*Consulting Physician to the Garfield Memorial Hospital and to the Providence Hospital.*

It has been accepted by the profession, until very recent years, that the treatment of diabetes was satisfactory which reduced the sugar output to a moderate percentage, prevented much acidosis, neuritis, subjective symptoms and escaped coma. Only of late has any physician suspected an ideal treatment with the highest result, as distantly possible. That extraordinary benefits to the organism could come from continued absence of urinary sugar, or that the hope might be entertained of practically continuous aglycosuric conditions, with possible absolute cure, was scarcely conceivable.

Once, however, the idea is established, that nearly every patient can be made sugar-free and kept so, while following a definite plan of diet, the interest and enthusiasm of both doctor and patient, and the self-education and coöperation of patient are inevitable.

Guelpa read a notable paper before the British Medical Association in July, 1910, entitled "Starvation and Purgation in the Relief of Disease," recently reviewed by Kellogg. This article maintained that diabetes mellitus is due to auto-intoxication from intestinal putrefaction, which has never been proven, reporting many cases made sugar-free in short periods of time by frequent starvations; usually accomplishing this in two or three days, and demonstrating that repeated fasting periods caused in some instances permanent aglycosuria.

Bardet later stated, before the Société de Médecine, that Guelpa's discovery had "completely upset established ideas" as to diabetes. Guelpa also reduced carbohydrates and proteins and eliminated the dread of acidosis and coma for fasting diabetics. He changed intestinal flora (which has been proved), reduced arterial tension, relieved neuritis, and improved the general health.

Fasting, which in normal man produces acidosis, has no such influence in the glycosuric, excepting in very rare instances, as lately pointed out by Stillman. In the "green diet," von Noorden and Naunyn had earlier recognized the same principle, but had not emphasized the idea or employed it successfully. Allen has scientifically demonstrated it by animal and human experimentation. In 1914 he reported results in depancreatized animals, the duets remaining *in situ*, along with the small portion of retained pancreas, producing at will, by diet, all stages of diabetes. In his produced mild cases, by re-

\* Read before the American Climatological and Clinical Association, Washington, D. C., May 10, 1916. Congress American Physicians and Surgeons.

the prominent symptoms of the exudative diathesis, namely asthma, then we may find a condition closely related to the so-called thymic asthma just brought to your attention. Second is the prominent group with eczema predominating, and third the group with asthma. It may not be necessary that the connecting link between these be a demonstrable pathological lesion of the lymphatic tissue. There may be a biochemical relation. Pfaundler stated several years ago that the diet had a marked effect on causing these conditions, while digestive disturbances are common. To quote him, "Is it not possible that under certain conditions (an unfavorable predisposition as to the function of intestinal and cellular digestion) foodstuffs digested into the gastro-intestinal tract might act in the body like an antigen; if this should be the case, then it would be quite natural to assume that the lymphatic diathesis represents a kind of food allergy (food anaphylaxis)."

Schloss in 1912 showed that egg poisoning in children is a form of anaphylaxis. It is well known that eczema is made worse by excess of fats and carbohydrates, but some recent work goes to show that proteids often are an exciting cause. To come directly now to the question of child asthma, it has just been shown that certain proteids may bring on in a child so predisposed typical attacks of bronchial asthma. It seems to me that this subject of proteid anaphylaxis or sensitiveness to proteids is being widely opened up, and that we are at a point of view of great importance. Whether there is any relation between lymphatism and proteid anaphylaxis is a very open question. Talbot has studied infants in relation to proteid anaphylaxis to asthma. The sensitization apparently takes place either by the unchanged proteid passing directly into the blood through the intestinal mucous membrane in the earliest weeks of life, or through the injured intestinal mucous membrane in later infancy during some digestive upset as diarrhoea. There may be also an inherited sensitiveness. The infants are tested by scarifying the skin and rubbing in the suspected proteid. Several foods may be tested at once on as many scarifications. Egg white, various kinds of meats, beef juice, milk for the casein, various grains such as barley and oat meal for the gluten, etc., are used. Within 15 minutes a small wheal or an erythema arises where the causative proteid was inoculated. Talbot has found that various proteids are the factors in many cases of child asthma, egg being the commonest cause. After the egg is found to be a cause, the asthma ceases on withdrawing the egg from the diet. This, of course, is a most inconvenient procedure, so he has attempted to accustom the child to egg by starting with one milligram doses of egg albumen in capsule by mouth, with increasing amounts, and he has met with success which is, however, if not complete, encouraging.

My personal experience is rather limited. One

child with an idiosyncrasy to egg, manifested by urticaria and eczema, had a typical attack of bronchial asthma. Attempts to immunize her brought on oedema with the third milligram dose of egg albumen. Another older boy had partial relief from his asthma when beef, to which he reacted, was withdrawn from his diet. The most striking case was a child of a year of age. At nine months she had had a good deal of mucus in her movements so at this time she may have become sensitized. About every three weeks she would have an unaccountable attack of mucous colitis and either asthmatic bronchitis or asthma. It took several attacks before we realized the attacks were true asthma and not primarily recurrent infections of the bronchial mucous membranes. Attempts at regulation of the diet were unavailing, for apparently what agreed with her at one time did not at another. Finally, by testing the skin with all foods she was taking that contained proteid, it was found that her troubles were due to beef juice. After withdrawal of this she had practically no more asthma, although she had a few more attacks of mucous colitis due to an apparent sensitiveness to milk proteid. But after her diet became more varied she showed marked improvement in this condition also. Here it seemed that it took the accumulation of two or three weeks of daily portions of beef juice before sufficient poison was at hand to bring on an attack, a condition somewhat different from the egg cases where perhaps one morsel of food containing egg may bring on asthma.

## GUILLAUME DE PUYTREN, 1817-1890

By WILLIAM FRANK COLE, M.D., B.S.

It has been said that "the greatest physician in America" was a Frenchman, and of some subject he was especially interested in that he could not go far in his studies without coming to him. That subject was medicine, and he, a German, I would say, was a Frenchman.

what as regards surgery at least, and say that if there was any modern surgeon especially interested in certain pet theories and principles, seemingly of modern times, that if he would but look back he would find that much of the work had been done by a Frenchman nearly a hundred years ago, and that Frenchman was Guillaume Dupuytren.

In the present age of telephones, motor cars, and dictagraphs, not to speak of the many instruments of precision at the service of medical men, to make their work easier and more exact, it is wise to look back and see what was accomplished by the great men of the early part of the last century, without these aids to our science.

Among the names of the many great French surgeons of the last century, that of Dupuytren stands first. In France the mutterings and rumblings of the great storm that was soon to break in the form of the Revolution, were growing louder and more insistent at the time of the birth of Dupuytren in 1777. Is it a coincidence that so many of the great medical men of France, hardly any of them from the aristocracy, were born at about this time? Malgaigne, Velpeau, Roux, Larrey, Dupuytren,—what names for a nation to be proud of and cherish! A study of the lives of such men as these leaves no room for doubt as to the cause of the wonderful powers of France, in her hour of need in the present great European struggle.

Guillaume Dupuytren was born at Pierre-Bouffiere, a town of Haute-Vienne, on October 5, 1777. (Some authorities give October 5, 1778.) His father was an advocate of very limited means, and though some accounts tell us of medical forbears, nothing definite is stated concerning this question. History tells us that, as a boy, Dupuytren was of more than ordinary attractive appearance and charm, and it is pretty definite that on account of this unusual personal attraction, he was kidnapped, when of tender age, by a rich lady of Toulouse; he was, however, returned to his family in a short time. In 1789, a cavalry officer who was stationed at Pierre-Bouffiere took a great fancy to the boy and it did not take a great amount of urging to obtain the permission of the elder Dupuytren to allow the boy to accompany him to Paris. On arrival at Paris, he was sent to the College of La Marche, which was directed by Monsieur Coësson, a brother of the officer. It was said that the young student particularly distinguished himself in philosophy while there, but from the evidence at our disposal, it seems that he was not in the least the "goody" type of boy, and got into all the scrapes and troubles that a normal boy should.

At about the time that the Revolution came to an end, Dupuytren was old enough to think of his definite career in life, and unhesitatingly chose the profession of medicine. He was hardly eighteen years old when he was chosen prosec-

tor at the École de Médecine, and in 1801 he was promoted to the position of "Chef de Travaux Anatomiques." We know that about this time he also paid great attention to the study of physiology and pathology, and this, as will be seen later, was of lasting value to him in his later work. In 1804, Dupuytren obtained one of the positions he had been striving for, and was appointed surgeon of the second class at the Hotel Dieu, where almost all of his work was done.

Malgaigne tells us some interesting anecdotes of the early days of Dupuytren in Paris, and apparently it was against his parents' wish that he stayed there. We know that his requests for money to keep on with his work were not granted by his parents. In his early struggles, which were almost unbelievably hard, like Velpeau's and Malgaigne's, he received a call one day from that great philosopher, Saint-Simon, who had become interested in the boy, probably on account of his bent for philosophy. He found Dupuytren working in bed on account of the cold, and other signs of abject poverty could not fail to be read. After a brief visit, Saint-Simon departed leaving a roll of bills amounting to two hundred francs on the barren mantel. Dupuytren soon saw the money, dressed quickly, and was soon at the house of Saint-Simon with it. He found the great man at home and said, "Here is something you forgot at my house." Saint-Simon could not tell the poor student the truth, and so after a moment said, "Yes, I forgot them."

The years that followed were indeed hard ones, probably no present day physician can form any conception of them. Much of the latter day bitterness and reserve of the great surgeon was undoubtedly on account of the indelible impress of the terrible times through which he passed in his youth. At one time, during his early life in Paris, his funds got so low that he had to subsist on bread and cheese for six weeks, but his determination to surmount all obstacles made him suffer all and endure all with fixed determination. It was at this time that he used the fat of the subjects in the dissecting room to make oil, with which to light his poor lamp. It might be said that fat, a substance abhorred by all dissectors, was never used to better purpose.

Stories conflict as to the exact facts regarding Dupuytren's first appointment at the Hotel Dieu, but there is no question as to the exceedingly bitter struggle for the place between Dupuytren and Roux. One story is that there was a *concours* for the place of third surgeon, a position that had never been existent until this time, and it was supposed by some that this was created expressly for Dupuytren, whose great operative skill was just beginning to be recognized. Roux determined to contest the position, and his examination proved to be equally good with that of Dupuytren. The de-

**CASE 3.** This case is reported for what it is worth; the striking result being sufficient justification. The patient was a boy aged three days. Born after normal labor, he had a violent convulsion when only a few minutes old, and these continued at the rate of five or six daily. Prominence of the upper portion of the chest suggested the possibility of enlarged thymus as the causative agent. The child was brought for examination at 7.30 p.m., having had a convulsion at 5. It was very weak and ap-

subject was purposely omitted. It should be begun lightly and increased if results do not follow. The writer's average has been from two to three minutes with a hard ray, filtered thru aluminum.

The writer's thanks are due to Dr. Maynard Ladd of Boston, Drs. G. M. Allen, M. Lincoln and A. W. Marsh of Worcester for the privilege of reporting the cases here cited.

CASE II.—Dr. Maynard Ladd.

peared to be nearly in extremis. Roentgenogram, rather hastily taken on account of the child's condition, showed a suspicious shadow in the upper mediastinal region. A treatment as vigorous as seemed safe was at once given. The child rested well that night; at 5 a.m. the next day had a little twitching of the eyelids but no convulsions. Began to nurse normally. Three treatments were given at three-day intervals. No more convulsions occurred and the child at once began to develop in normal way, which improvement has continued to the present,—6 weeks after the last treatment.

Dosage varies so much that discussion of it

is not warranted. The treatment was given by the writer, who has had no previous experience with it. The first treatment was given at 7.30 p.m. on the day of admission. The second treatment was given at 7.30 p.m. on the third day. The third treatment was given at 7.30 p.m. on the sixth day. The fourth treatment was given at 7.30 p.m. on the ninth day. The fifth treatment was given at 7.30 p.m. on the twelfth day. The sixth treatment was given at 7.30 p.m. on the fifteenth day. The seventh treatment was given at 7.30 p.m. on the eighteenth day. The eighth treatment was given at 7.30 p.m. on the twenty-first day. The ninth treatment was given at 7.30 p.m. on the twenty-fourth day. The tenth treatment was given at 7.30 p.m. on the twenty-seventh day. The eleventh treatment was given at 7.30 p.m. on the thirtieth day. The twelfth treatment was given at 7.30 p.m. on the thirty-third day. The thirteenth treatment was given at 7.30 p.m. on the thirty-sixth day. The fourteenth treatment was given at 7.30 p.m. on the thirty-ninth day. The fifteenth treatment was given at 7.30 p.m. on the forty-second day. The sixteenth treatment was given at 7.30 p.m. on the forty-fifth day. The seventeenth treatment was given at 7.30 p.m. on the forty-eighth day. The eighteenth treatment was given at 7.30 p.m. on the fifty-first day. The nineteenth treatment was given at 7.30 p.m. on the fifty-fourth day. The twentieth treatment was given at 7.30 p.m. on the fifty-seventh day. The twenty-first treatment was given at 7.30 p.m. on the sixtieth day. The twenty-second treatment was given at 7.30 p.m. on the sixty-third day. The twenty-third treatment was given at 7.30 p.m. on the sixty-sixth day. The twenty-fourth treatment was given at 7.30 p.m. on the sixty-ninth day. The twenty-fifth treatment was given at 7.30 p.m. on the seventy-second day. The twenty-sixth treatment was given at 7.30 p.m. on the seventy-fifth day. The twenty-seventh treatment was given at 7.30 p.m. on the seventy-eighth day. The twenty-eighth treatment was given at 7.30 p.m. on the eighty-first day. The twenty-ninth treatment was given at 7.30 p.m. on the eighty-fourth day. The thirtieth treatment was given at 7.30 p.m. on the eighty-seventh day. The thirty-first treatment was given at 7.30 p.m. on the ninetyth day. The thirty-second treatment was given at 7.30 p.m. on the ninety-third day. The thirty-third treatment was given at 7.30 p.m. on the ninety-sixth day. The thirty-fourth treatment was given at 7.30 p.m. on the ninety-ninth day. The thirty-fifth treatment was given at 7.30 p.m. on the one hundredth day.

find the general condition behind it if we are to get anywhere. In looking around, one of the general conditions which we run across is the so-called lymphatic constitution and this is what I first want to discuss in its relation to asthma.

Three states of childhood are spoken of together, namely, the lymphatic constitution, neuro-arthritis and exudative diathesis. Whether they are entirely different conditions or different manifestations depending on the pre-

and a sensitiveness of the respiratory mucous membranes. Many other symptoms are often present, such as an intermittent fever, chills, perspiration, adenoids and swelling of the tonsils and glands of the throat, jaw and neck, anemia, pseudo-hypertrophy of the heart with palpitation or arrhythmic pulse; a tender skin, urticaria, intertrigo, crusts on the face and scalp, eczema; coryza, hay fever, laryngitis, diffuse tracheo-bronchitis, bronchiolitis and bronchial

CASE II. After treatment. Showing diminution in thymus shadow.

dominating symptoms of the same condition is not clear, but probably if the latter is not true then at least they stand in close relation to each other. We differentiate the pastous or lymphatic system and a stupid temperament; the erythric or neuro-arthritis habitus, restless and irritable with tender skin, and rather precocious intelligence, and the plethoric obese habitus, babies of tremendous adipose tissue. The general signs and symptoms are a hyperplasia of the lymphatic system, a sensitiveness of the skin,

asthma; a coated tongue, geographical tongue, habitual constipation with muco-membranous enteritis and cyclic vomiting. This is only a partial list of the symptoms and as these symptoms go with other conditions, it shows the complications and uncertainty of their relations.

On one extreme we have the predominating lymphatic type, and it is probable that so-called lymphatism or status thymico-lymphaticus with hypertrophied lymphoid tissue, enlarged spleen and thymus, with tendency to sudden death is the same condition. If to this we add one of

Bulging of the upper part of the chest has also been observed.

Sylvester,<sup>15</sup> of Boston, makes a distinction between the symptoms of cyanosis, stridor, and slow, labored breathing, and those of breathing of the asthmatic type, characterized by fairly easy inspiration and long, difficult expiration accompanied by râles. The first syndrome he ascribes to pressure, the latter to hypersecretion of the thymus.

In differential diagnosis, incoordination of the vocal cords, malformation of the larynx, and when occurring some time after birth, enlarged bronchial glands, adenoids, and swallowed foreign bodies must be ruled out.

The diagnosis is usually best made from a good Roentgenogram, when the enlarged gland appears as a broadening of the upper mediastinal shadow to right or left, or both. An enlargement to the right may be due to other causes, but with broadening to the left, the diagnosis is reasonably certain.

Too much dependence, however, must not be placed on the x-ray. The "critical space of Graetz," as that writer named the superior opening of the thorax, is in young infants less than 2 cm. in diameter, and a very slight antero-posterior enlargement of the gland in this region is sufficient to produce pressure on the trachea, esophagus, and all other structures which pass this point. Diagnosis in such cases, accordingly, must rest on the clinical symptoms.

The first method of treatment proposed was, naturally, surgical removal. The work of Rehn has already been mentioned. Later, resection of the manubrium was tried, and finally thymectomy. Andrews,<sup>16</sup> writing in 1913, claimed that simple ablation of the gland could be done without much risk. Parker's<sup>17</sup> report of 50 cases, however, published about the same time, showed a mortality of 33.1-3%. It is interesting to note the change of heart shown by Veau,<sup>18</sup> a French surgeon, who was a pioneer in the work and to whom were credited 11 of Parker's 50 cases. In 1912 he reported to the Paris *Pédiatrie* Society two cases of his own treated by the Roentgen method, and stated, "for over a year I have not done a thymectomy, and have not yet been disappointed in radiotherapy." It will presently be shown that the latter method obviates even the slight risk claimed by Andrews, and from a practical standpoint it must be admitted that consent to a non-surgical method is much more easily secured than for surgery on patients of such tender age.

The high percentage of mortality from surgical intervention, together with the known success of the Roentgen ray in destroying other structures of a lymphatic nature, induced a trial of this agent. The first case reported was that of Friedlander and Crane,<sup>19</sup> at Cincinnati in 1904. In 1907 Rudberg,<sup>20</sup> by experiments on animals, showed that it was possible to induce all grades of shrinking in the gland, up to the point

of complete fibrosis and destruction of all gland tissue, by action of the ray. Sidney Lange,<sup>21</sup> of Cincinnati, working independently at about the same time, confirmed these results, showed that it was possible to vary the rate of the atrophy by varying the intervals and intensity of the irradiation, and in 1910 he reported to the American Roentgen Ray Society a series of five cases successfully treated. Further confirmation was given the method by the report of Ribl-dean's<sup>22</sup> case, in which, after intensive irradiation had caused the disappearance of the dyspneic symptoms within a few days. The child died later of measles; the autopsy showed fibrous atrophy of the thymus gland. Lange's last report, presented before the Roentgen Ray Society in 1913,<sup>23</sup> included 30 cases from his own and other clinics, in every one of which the application of the ray was followed by prompt and complete recovery. Among later case reports may be mentioned those of Sylvester<sup>15</sup> and of Morgan and Daehler.<sup>24</sup>

The contrast of these excellent records with the one-third mortality of thymectomy would seem to be sufficient argument for Roentgenotherapy, but there is still further evidence to be cited. The objections raised by the advocates of surgical treatment are, first, that the slow action of the ray renders it unsuited for urgent cases, and second, that the gland tends to regenerate rapidly after involution produced by the ray. Rudberg, however, in his experiments already cited, found involution beginning 3½ hours after the first exposure. Lange, in at least one urgent case, was able to bring about a symptomatic cure by one massive treatment. His patient was in such condition that tracheotomy had been done prior to its admission into the hospital. He does not claim that the thymus under these circumstances has undergone complete involution, but simply that its size and function have been decreased sufficiently to tide the patient over a dangerous period. In the milder cases one massive application has produced a symptomatic cure.

The second objection, that of tendency to regeneration, can with justice be brought against surgical treatment as well. The serious results of complete thymectomy in animals have been chronicled. Parker, the advocate of surgical treatment already mentioned, gives as his opinion that the removal of small bits of the gland directly concerned in the production of pressure is as effective as that of larger portions. He believes further that complete thymectomy is practically impossible in the human being. From one of his own cases he quotes the following: "I followed a fairly cooperative case of the case of Kase and Vogt's report, in which the thymus gland was completely removed, and the child died of pneumonia. The autopsy showed that the thymus gland had regenerated to its normal size and function, and that the pneumonia was due to the regrowth of the gland." This is a strong argument in favor of the Roentgen method, which does not destroy the gland completely, but merely reduces it to a size and function which will not produce pressure.

spect to regeneration, but if this occurs after Roentgentherapy it can readily be controlled by repetition of the treatment.

The possibilities of this method of treatment will doubtless be found to increase as our experience with it grows. It is believed by many that there is a connection between enlargement of the thymus, adenoids, and hypertrophied tonsils, and the thymus condition may well be as common as the other two. The irradiation of all suspicious cases might save them from death under an anesthetic or intercurrent infection occurring before the third year, at which time spontaneous relief usually occurs. Even the acute symptoms may not be manifest in every case. The thymus is always a potential source of danger and possible cause of death.

The interrelation of enlarged thymus and hyperthyroidism is now pretty generally recognized. Autopsies on cases of Graves' disease show enlarged thymus in 75%, and in the cases dying after operation the proportion was found at Munich to be even higher. The exact rôle played by the thymus, whether a casual factor or a direct cause of death remains to be worked out. Hector McKenzie, quoted by Parker, found the thymus enlarged in all his cases of Graves' disease that came to autopsy, and suggests that possibly every case in which there is a thymus persisting into adult life is one of potential or latent Graves' disease. For some years the Mayo clinic, among others, has used preoperative irradiation on their cases of exophthalmic goitre, and it may well be that the beneficial effects have been due to the action of the rays on the thymus instead of the thyroid. As an example of thymus hypertrophy in adult life, Lange quotes the case of a woman of 35, suffering for one year with palpitation and choking sensations, increasing so that swallowing and breathing became difficult. X-ray examination disclosed what was believed to be an enlarged thymus. One massive treatment gave relief, after which improvement was progressive.

The excellent article of Lange has already been liberally drawn upon in the preparation of this paper. His deductions, however, are so well-phrased that I shall venture to quote them in conclusion:

1. Roentgen irradiation of the thymus produces artificial involution of the gland.
2. X-ray therapy is the method of choice in cases of enlarged thymus in children, whether the symptoms be mild or urgent.
3. Urgent cases should receive repeated massive doses.
4. Recurrences due to regeneration of the gland are to be watched for and controlled by further treatment.
5. Children whose physical or mental development is retarded should, if suspicion is directed toward the thymus, receive tentative x-ray

treatment, even though a positive diagnosis cannot be established.

6. X-ray therapy as a precautionary measure, or preoperative treatment may enable children of the so-called lymphatic type to withstand intercurrent disease or anesthetics, which would otherwise prove fatal.

7. Pre-operative exposure of older children and adults, where there is a suspicion of enlarged thymus, might lessen operative mortality.

8. Routine pre-operative x-ray treatment in cases of hyperthyroidism should be resorted to with a view to lessening operative mortality.

9. X-ray exposure of the thymus gland has been proven harmless, whether in normal or abnormal individuals. A therapeutic test with the x-ray is, therefore, always permissible.

#### REPORT OF PERSONAL CASES.

CASE 1. Boy aged ten weeks. Born after normal labor. When ten days old had sudden attack of dyspnea and collapse, which recurred frequently at intervals of a few days, and rendered the constant presence of two nurses necessary. X-ray examination was inconclusive, but on the basis of clinical symptoms Roentgentherapy was decided on. Five treatments were given at five-day intervals. After the first exposure the suffocative attacks ceased and the child began to develop normally. At the age of eight months adenoids were removed under light anesthesia, with complete success.

CASE 2. Boy aged 20 months. Weight at birth, 7¼ lbs. at 1 year 24½ lbs. The nurse who attended his mother at birth states that for the first few days the child was constantly troubled with accumulation of mucus in the throat, requiring much attention. Thereafter he developed rapidly and had no sickness during first year. During the fall of 1914 he began to catch cold easily and often. This was noticeable as he had been so free from colds during his first year. He developed a spasmodic cough, so that whooping cough was at first suspected. This cough and a wheezy asthmatic breathing continued throughout the winter. At times it seemed to be controlled by full doses of belladonna. In January, 1915, adenoids were removed, without marked benefit. He was then sent to Atlantic City to see if the change of air would help him. It did not. Dr. Hollinghead, of Philadelphia, then suggested a Roentgenogram.

X-ray examination by Dr. W. S. Newcomet of Philadelphia revealed enlarged thymus, also marked enlargement of right pulmonary hilus shadow. Von Pirquet test positive. X-ray treatment was ineffective until the dosage was increased, when improvement began. A Roentgenogram taken after three months shows marked diminution of thymus shadow. This child's general condition continues to improve, and he has no severe suffocative attacks. At times, however, stridor and dyspnea reappear in some degree, and an occasional treatment is given. In a personal conversation with the writer, Dr. Newcomet stated that he considered this case to be one of the so-called "glandular babies," and advised vigorous raying over large areas of the chest. This advice is now being followed.

## ROENTGENTHERAPY IN HYPERTROPHY OF THE THYMUS GLAND.\*

By PHILIP H. COOK, M.D., WORCESTER,

Röntgenologist, City and Memorial Hospitals; Physician to Out-patients, City Hospital, Worcester.

IN no line of recent medical research has greater interest been taken, nor more fruitful results obtained, than that pertaining to the ductless glands. Each of these organs by its separate action, and by its interrelation with others, has been shown to have effects upon the bodily economy which present a problem at once perplexing and fascinating to investigator and clinician alike. And some of the most interesting clinical questions centre about the thymus gland.

**Anatomy and Development.** In man the thymus develops as a paired organ from the ventral part of the third branchial cleft, at birth the organ lies behind the sternum, backward as far as the pericardium, reaching above so high as higher than the jugular notch. Accessory lobes lying within the thyroid or closely united with it may develop from the main organ. "The close association," says Noel Paton, "of such a structure with the original direct organ of the blood-flow to the body suggests the occurrence of some modification in the blood current for the tissues." This statement should be borne in mind when discussing the clinical physiology of the gland.

It consists of two lobes, each of which is lobulated, and each of which is composed of small globules. The lobules are separated by thin capsules, and the capsule of the whole gland is composed of a thin layer of connective tissue. The gland is situated in the upper part of the thorax, behind the sternum, and in front of the heart.

The gland is situated in the upper part of the thorax, behind the sternum, and in front of the heart. It is situated in the upper part of the thorax, behind the sternum, and in front of the heart. It is situated in the upper part of the thorax, behind the sternum, and in front of the heart.

called corpuscles of Hassall. They are invaded by polymorphonuclear leucocytes, and their protoplasm contains granules staining deeply with basic stains. The interstices of the epithelial groundwork are filled with lymphocyte-like cells, the nature of which is still under dispute, one school of writers asserting them to be true lymphocytes derived from outside, the others to be derived from the epithelial cells and hence really epithelial in nature. Upon this point depends, in large measure, the classification of the gland in its relation to the bodily economy, whether with the lymphatic apparatus, as was formerly supposed, or with the system of hormone producers. Without attempting to take sides in the controversy, it may be remarked that it is against these cells that the Roentgen-therapist in large measure directs his efforts, and that they react like other structures of known lymphatic character.

In man, as in most other animals, the thymus reaches its greatest size in relation to the body at the time of birth; thereafter it continues to grow, but at a reduced rate, growth ceasing only with the beginning of sexual maturity; it then atrophies, the essential tissue being replaced by fibrous tissue and fat, and is finally reduced to a mass of adipose tissue with a few islands of thymus remaining.

*Physiology.* That the secretion of the organ is essential to the normal development of infancy and early childhood seems definitely proven. Klose and Vogt,<sup>2</sup> by splitting the sternum, removed the thymus from 54 dogs. All the operated animals died in from three to seventeen months, after passing through certain definite stages. After a short latent period, characterized by ravenous appetite, they passed into a second stage of adiposity, in which they became heavier than their controls, with apathy and muscular weakness. Soon, however, the third stage of illiata thymica supervened, the animal becoming cachectic, clumsy, and stupid. A coma of several days followed, ending in death. The most important developmental variation in these thymectomized animals was found to lie in the small size of the skeleton and poverty of lime salts in the bones. The changes were those of osteoporosis and osteomalacia. In delayed ossification and diminished lime content they somewhat resembled rachitic change. The experimenters ascribed these conditions to a nucleinic acid intoxication, normally neutralized by thymus secretion.

The experiments of Svehla,<sup>3</sup> who by injection of watery thymus extract produced lowered blood pressure and eventual death in dogs, have been largely discounted by Popper<sup>4</sup> and other later workers, so that the effect of hyperthymization must be considered from the experimental standpoint is still unknown.

The interrelation of the thymus with other glands is beyond the scope of this paper. It is interesting in passing, however, to note its rela-

tion to the sexual organs. It had long been known by butchers that the thymus of castrated cattle was larger than that of bulls. Henderson, at the request of Noel Paton,<sup>5</sup> investigated this point. He found that the thymus of the castrated was nearly twice the size of that in uncastrated, and that its atrophy is delayed.

*Symptoms and Treatment.* In 1829 Kopp first described a disturbance of respiration due to persistent or enlarged thymus, which he ascribed to pressure upon the trachea. In 1858, however, Friedleben<sup>6</sup> stated very emphatically that "enlargement of the thymus is not to be considered as a cause of death." This pronouncement by so eminent an authority undoubtedly set back progress along this line for many years. In 1888, Grawitz reported two sudden deaths in infants, in which the autopsy disclosed an enlarged thymus. This was closely followed in 1890 by Paltauf's<sup>7</sup> description of the so-called "status lymphaticus," in which, he believed, though the thymus was enlarged in every case, the enlargement was not the cause of death. Hedinger,<sup>8</sup> however, in 18 autopsies on cases of thymus death, proved pressure in each case. Beneke<sup>9</sup> showed that the simple throwing back of the head was sufficient to produce pressure, and Jackson,<sup>10</sup> in 1907, demonstrated by bronchoscopy, direct pressure upon the trachea in a case of enlarged thymus without any accompanying signs of status lymphaticus. At about the same time Rehn,<sup>11</sup> by excising a piece of the gland and thus relieving the symptoms, proved them to originate from pressure. Not only may the thymus compress the right or left auricle, but by displacing the blood vessels cause irritation of the inferior laryngeal nerve, and thus cause spasm of the glottis, according to Crofti.<sup>12</sup> This, accordingly, is the view held by most observers today, despite some arguments for the internal secretion theory.

As seen in man, the pathology is practically always that of a simple hyperplasia. New growths occasionally occur, and congenital syphilis is believed by some to have a part.

The characteristic clinical syndrome of this affection is the so-called "thymic asthma,"—sudden severe attacks of dyspnea, stridor and suffocation. Most common in early infancy, it may occur as a sudden complication in other diseases in older children, in whom it may be a cause of sudden death. This latter condition is termed by D'Oelsnitz,<sup>13</sup> who first described it, as "latent hypertrophy of the thymus." Holt<sup>14</sup> recognizes thymus hypertrophy as a possible cause of convulsions in infants, without other signs. The dyspnea is of the expiratory type,—the stridor inspiratory. In many cases diagnosis can be made by percussion, the thymus presenting a roughly shield-shaped area of dullness, broadest above, and merging into the heart dullness below by an isthmus which varies in length and breadth according to the degree of hypertrophy.

The conclusions are as follows.

a. The laminaria salpingitis is characterized by its hemorrhagic tendency, its leucocytic pus and the absence of lymphocytes and plasma cells. The process is not always limited to the endosalpinx and may resemble phlegmonous inflammation of the wall of the tube.

b. Tuberculous salpingitis can easily be distinguished by the histological changes except in the very early catarrhal form in which the diagnosis rests only on the presence of the tubercle bacilli.

c. The salpingitis following appendicitis (endosalpingitis very rare) presents in itself nothing characteristic. Generally it is a perisalpingitis easily made out under the microscope.

d. In the acute stage of gonorrheal salpingitis there is a striking accumulation of plasma cells and of lymphocytes in the tissue and in the pus, by which early gonorrheal processes can be distinguished from septic processes. In the subacute and in the chronic stages the histological picture is nearly always characteristic for the gonorrheal and for the septic forms, but occasionally septic organisms produce adhesions of the endosalpinx and plasma cell infiltration. The character of the pus is distinctive, lymphocytic and with plasma cells in gonococcus infection, and leucocytic in septic cases. Yet a diagnosis is not always to be made by mere examination of the pus, for secondary infections are possible and do occur. In general, therefore, Wædtjen supports Schridde's views.

#### CONSERVATION OF THE TUBES.

Loehberg<sup>9</sup> reports a series of cases in which plastic operations on the uterine tubes were performed. The procedure was introduced into operative gynecology in 1885 by A. Martin, who designated it salpingo-stomato-plasty, meaning the opening by plastic operation of the abdominal tubal ostium which had been closed by inflammatory process, so as to give a permanent opening with permanent restoration of function. Skutsch advocated the term salpingostomy, which has persisted in general use.

The number of cases reported from various clinics has fallen off considerably in recent years, and little attention is paid to the operation in textbooks. The results have not been satisfactory as regards facilitating impregnation, for which various causes have been assigned. The tube may have been closed at the uterine end also, or the opening did not remain patent, through the formation of other adhesions. The disease, in the first place, having come from a gonorrheal infection, may have rendered the husband incapable of begetting children.

The danger of extrauterine pregnancy in the repaired tube has been emphasized, but as a matter of fact it is very slight, according to Loehberg. The only case reported was in a patient operated on for extrauterine pregnan-

cy; a plastic operation was performed on the closed tube of the other side, with a second extrauterine pregnancy about a year later. The actual number of cases of pregnancy is very small. The results, however, as far as secondary operations are concerned, are favorable, the mutilated tube rarely demanding another operation.

The series reported by Loehberg consisted of twenty-one cases, over a period of five years, and subjected to later examination as far as possible. The indications for operation are chronic inflammation without much obvious disease of the tubes, as marked distention from hydrosalpinx. Perisalpingitis with little disease of the tube would be favorable. Acutely inflamed tubes should not be operated upon, and if pyosalpinx is present on one side, no plastic operation on the other side should be attempted. The convalescence in the cases reported was about as in cases of salpingectomy. In two cases the abdomen was opened later, three and five years after operation, for conditions not connected with the pelvis and the tubes were found to be closed again. Only fourteen cases could be traced.

The subjective symptoms were much improved as a result of the operations, which had in fact been other than simple salpingostomies. Examination showed all but two cases to be normal; these had small masses in the position of the tubes. No pregnancy had ensued, either intra- or extrauterine.

The cause of the failure of these operations, Loehberg attributes to the technique of operation, the difficulty of obtaining an opening of the tube which is permanent and adequate to receive the ovum. The methods employed were splitting the tube, excising a piece to form a fenestra, cutting off the closed end of the tube, in all cases suturing the mucous membrane and peritoneum together and fixing the end of the tube to the ovary.

In spite of these bad results, Loehberg thinks the operation is indicated as a cure for sterility, (1) if the wife alone is at fault, and the history and findings suggest closure of tubes by inflammation; (2) as a conservative operation in disease of the tubes, of a chronic character, without much injury to the tube itself and always in young persons.

#### CAUSE OF TUBAL PREGNANCY.

Mall<sup>10</sup> presents a preliminary report on the cause of tubal pregnancy based on a study of one hundred and seventeen specimens. He gives a detailed account of the specimens in a later publication, Number 221, of the *Annals of the Entomological Society of Washington*.

Two aspects of tubal pregnancy are considered, the cause of the extrauterine pregnancy, and the fate of the closed ovary. The first aspect studied is so compact that it does not allow of condensation, but certain points may be noted. The cause of tubal pregnancy may be (1) a direct invasion

of specimens, which is accompanied by data bearing on the cause of tubal pregnancy, shows quite definitely that the condition is associated with inflammatory changes which must have preceded the lodgement of the ovum in the uterine tube." This inflammation affecting the tubal epithelium, or any other change which delays the ovum in its progress, will favor tubal pregnancy. Among these conditions are abnormal diverticula. To what extent inflammation outside of the tube interferes with the progress of the ovum in the tube is not clear. But it is found that "if the ovum within the tube contains a normal embryo, there is but little adjacent inflammation; if it contains a pathological embryo the changes in the tube are usually marked, and when the ovum is well disintegrated, the changes are still more pronounced. Read in the other way, this would mean that if the inflammatory condition is nearly healed, the ovum implants itself in the tube and grows normally, but if the results of infection are still pronounced, the ovum rapidly disintegrates. Such an inflammatory process is signalized not only by an inflammatory reaction in the tube wall, but also by very pronounced changes within the tube lumen, the most common of which is a condition known as follicular salpingitis."

"Another type of change differs markedly from follicular salpingitis, but in a way seems to go hand in hand with it. This condition may be spoken of as an outpocketing of the epithelial lining" into the muscular coat. According to the situation and extent of the pathological changes implantation occurs in the outer, middle or inner portion of the tube.

On the character of the etiology of the inflammation, the study of the specimens throws no light. But the history of the cases points strongly toward venereal disease as the chief cause of tubal pregnancy, though an infection at a previous labor is apparently the cause occasionally. For the extremely interesting discussion of the fate of the enclosed ovum, reference must be made to the original article.

#### VULVOVAGINITIS AND GONORRHEA IN CHILDREN.

Wolfenstein<sup>11</sup> reports briefly the results of treatment of gonorrheal vulvovaginitis in children. A point which he investigated with great care is the frequency with which there occurs at the same time gonorrheal infection of the rectum. In his series the percentage was fifty-four; the highest figure hitherto reported was thirty-eight. For this discrepancy, Wolfenstein is inclined to think that repeated examinations, during the whole course of the treatment of the vulvovaginitis, are responsible. In about one-half of the cases the diseases coincided at the beginning of the treatment; in the other half positive results were found on examination from eight days to eight weeks after the beginning of treatment. Generally the course of the rectal infection is without symptoms. In the

chronic cases there may be palpable and permanent lesions, as stricture, but the chief danger is that of reinfection of the vulva and vagina. The results of treatment tested by bacteriological examination indicate that in this situation the disease is at least as resistant as in the vulva and vagina. Of the cases under treatment, nearly all were finally discharged cured without permanent injury. On account of the danger of infecting the vulva and vagina, the rectal condition should be given treatment with silver salts.

Taussig<sup>12</sup> contributes a careful study of the prevention and treatment of vulvovaginitis in children. Reports from various cities indicate that this disease is not at all infrequent and bacteriological examination shows that nearly always vulvovaginitis in children is gonorrheal. A series of two hundred and sixty-two patients coming to a dispensary for various conditions was examined with reference to the presence of a discharge. If a discharge was found, examination was made for the gonococcus and it was detected in fourteen cases. In very few cases did the patient come on account of the discharge.

A study of the sixty-six sporadic cases in Taussig's series of gonococcal infections indicates that the source of the infection was rarely the parent, rarely from possible rape, rarely from infected clothing or from the bath, and rarely from other children by direct contact. The lavatory seat in the school seems to be the chief source of infection. Forty-seven of the sixty-six were of the school age.

The symptoms do not often cause much discomfort and the mother first notices the discharge. Occasionally ophthalmia or arthritis is the first manifestation of the disease. In the acute stage the patient may complain of burning on micturition or increased frequency.

In the way of treatment, Taussig recommends for the first two weeks rest in bed as much as possible, with vaginal instillations of twenty-five per cent. argyrol twice a day. For the third and fourth weeks, daily instillations of one per cent. silver nitrate; for the fifth and sixth weeks, two per cent. silver nitrate once in two days and from the seventh to the tenth weeks, four per cent. silver nitrate twice a week. In keeping up the systematic treatment the visiting nurse association has given valuable aid. The prognosis is generally favorable in time, but it is difficult to say just how soon a case will be cured or when it is actually cured. Ultimate danger to the child is probably not great, though occasionally a serious complication follows.

Prevention is the most important. Taussig's suggestions are as follows:

(1) Instillation of two per cent. solution of silver nitrate into the vestibule of all new born girls whose mothers show evidence of gonorrhea. Probably but a small number of infections come

the uterine cavity. The uterine wall was then closed over it and its pedicle.

Nine months later, on account of some increased pain in the pelvis and a mass on the right side of the uterus, the patient was operated upon again and the piece of ovary which had been left *in situ* was removed with a cyst the size of a child's fist. Some time later the patient had the signs of early pregnancy, but at the middle of the fourth month there was a uterine hemorrhage, with the expulsion of a mass of detritus, presumably a miscarriage, though not confirmed by microscopical examination. The uterus, however, rapidly decreased in size and the other signs of pregnancy disappeared.

#### FATE OF THE OVARIES AFTER HYSTERECTOMY.

Vineberg<sup>4</sup> discusses the fate of the ovaries after hysterectomy. The matter cannot be settled by experimental studies for comparatively few cases of hysterectomy come to secondary operation, and experiments on animals are no more than suggestive as the anatomical conditions are not strictly analogous. Searching the literature with some care, Vineberg finds numerous articles and comments on the subject, but no marked agreement of opinion. In fact, in some cases the ovaries have undergone little or no apparent change even a year after hysterectomy; in others there is evidence of congestion; in a third group there is atrophy, and in some there is "cystic degeneration" and a tendency to the formation of adhesions.

It has been suggested that interference with the blood supply, occurring practically always in the human, is the cause of anatomical changes in the ovary. At the present time all that can be said is that the ovaries may or may not be affected but probably will be because of interference with the blood supply.

In considering the effect on the function of the ovary, we are again unable to arrive at a satisfactory conclusion because we do not know enough of the cause and nature of the climacteric. In certain cases, following operation, there are no symptoms of the climacteric. In certain cases without operation the symptoms of the climacteric are marked. While it may be true that the symptoms of the climacteric, following operation, are due to trauma of the pelvic sympathetic nerves at operation, this explanation does not hold for patients who have not been subjected to operation. It seems better to regard the cause of the climacteric symptoms as something as yet unknown, than to attribute them to something which does not explain all cases.

The value of Vineberg's paper lies chiefly in the support it gives to the other side if anyone makes categorical or sweeping statements as to the effects of leaving or removing the ovaries at hysterectomy.

#### CORPUS LUTEUM CYSTS AND MENSTRUATION.

It may be said that in general menstruation is not affected by cyst formation in the ovary. Halban<sup>5</sup> has noticed for some years that in certain cases of cyst development, menstruation ceases suddenly. Such a case might easily be mistaken for extrauterine pregnancy. This coincidence of ovarian cyst and amenorrhea is not accidental, but has a causal relation, for such cysts are corpus luteum cysts.

It seems probable that the corpus luteum exercises a restraining influence on the appearance of the menstrual flow. Halban and Kocher<sup>7</sup> found that the extirpation of the corpus luteum in the human female is followed by the appearance of the menstrual flow. If the extirpated corpus is implanted in the abdominal cavity, menstruation does not appear. It is true that the premenstrual changes in the endometrium are due to the corpus luteum, but bleeding does not appear until the influence of the corpus luteum is removed or is diminished.

The explanation of the cases to which Halban has called attention is that with the formation of corpus luteum cysts there is a persistence of the effect of the lutein tissue far beyond the normal period of time; as the cysts atrophy, and sometimes they spontaneously disappear, menstruation reappears and if an actively secreting cyst be removed, menstruation recurs.

This point may be of some diagnostic value and will influence treatment, for corpus luteum cysts rarely need operation because they have a tendency to regress. "Alternating cysts," that is, cyst development in both ovaries at different times with spontaneous disappearance, are to be regarded as corpus luteum cysts. They are thin walled and thus easily ruptured during examination. It has been found also that their extirpation during pregnancy does not cause interruption of the pregnancy.

#### NERVES OF THE OVARY.

As the result of his extensive studies which he describes in detail, Wallart<sup>8</sup> comes to the conclusion that the relations of the nerve supply in the germinal gland are by no means as simple as has been hitherto generally supposed. In spite of the care of his own studies, he says that final judgment is not yet to be passed on the matter. The great wealth of the ovary in nervous elements, and its manifoldness consisting of internal secretion capacity, as well as corpus luteum, interstitial glands, and perhaps the decidua-like formations during pregnancy, cause the ovary to appear as one of the most complicated and interesting organs of the female, inviting detailed investigation. The author's investigation, "The nervous system of the ovary to the post of the corpus luteum," is a study of attention, as of late been noted, in view of the emphasis placed on the importance of the nervous system in the development of the female sex.

ance, although at present it is not understood at all.

#### OVARY AND ABDERHALDEN REACTION.

Solowjew<sup>7</sup> has found that in every case in which the presence of pregnancy could be determined with certainty, the Abderhalden serum test was positive, but that in cases in which pregnancy was not present the test was sometimes positive and sometimes negative. In ten cases in which the serum was from men the test was negative, but in one case, a woman certainly not pregnant, the test was positive. This suggested to him the possibility of the reaction depending in some degree on the ovarian function, and in two girls who had never menstruated he found the test was negative. This recalls the report of Kjaergaard who found strong proteolytic action in the serum of women during the premenstruum.

#### SALPINGITIS.

Waetjen<sup>8</sup> presents a careful and thorough study of the histology of suppurative salpingitis and its relation to the question of etiology. Since Schridde's publication in 1910 on purulent inflammations of the tubes, there has been very active interest and some polemical discussion. His thesis that gonorrheal salpingitis presented a characteristic histological picture has been rejected outright by certain pathologists and gynecologists, and has received support in varying degree from others.

The forms of salpingitis investigated are: (1) following dilatation with laminaria tents. In this group were forty-eight cases, in seventy-five per cent. of which there was found salpingitis. The pregnancy had been interrupted on account of advanced tuberculosis of the lungs, in nearly every case, and the tubes had been removed to produce absolute sterility. Clinically, the introduction of the tent was entirely benign in this series, as in series reported by others, but sixteen cases showed slight inflammation (endosalpingitis only), fourteen moderate grade of inflammation involving the muscular wall of the tube also, and six severe inflammation though no ulceration was observed. In no case could the inflammation be traced to the gonococcus or to early tuberculosis. The histological picture also suggested that a complete *restitutio ad integrum* was likely to follow. In non-pregnant women the tents produced no salpingitis.

(2) Tuberculous salpingitis. Here there is little cause, histologically, for confusion, because of the typical changes produced by the tubercle bacillus, but two points should be noted. Even in purulent salpingitis with tuberculosis the tuberculosis may be secondary, on the basis of an old inflammatory process, as Simmonds has pointed out; and there may be found a "catarrhal" salpingitis with no characteristic changes,

histologically, but with tubercle bacilli present. One of Waetjen's cases was of this very early form. In two cases in which there was a characteristic change in the wall of the tube and pus in the lumen, no caseation was present and no plasma cells were found in the pus.

(3) Salpingitis ex appendicitide. There is a frank difference of opinion between clinicians and pathologists as to the frequency of the spread of inflammation from the appendix to the tube. The clinician claims it is a frequent occurrence; the pathologist holds it to be rare. That such acute inflammation may involve the tube from the appendix is exemplified by one case in Waetjen's series. Perisalpingitis secondary to appendicitis is not infrequent. That secondary endosalpingitis may be of serious grade so as to cause a destructive process or pyosalpinx, there is grave reason for doubting. But the case of a girl of sixteen with the history of attacks of appendicitis years before, and with traces of an old destructive process in the tube also, suggests that the endosalpingitis following appendicitis may be serious in nature. Practically always the inflammation following appendicitis shows involvement from the serosa inward and not from the endosalpinx outward. Waetjen is inclined to agree with Pankow who says: "In all inflammations and adhesions of the adnexae and pelvic peritoneum, in which septic or gonorrheal infection from the uterus, or tuberculosis, can be excluded, we shall find by the microscopical examination of the grossly normal appendix the cause of the otherwise inexplicable pelvic changes."

(4) Gonorrheal salpingitis. The histology of gonorrheal salpingitis has been most thoroughly studied and accurately described by Schridde and Amersbach, as even the opponents of their views acknowledge, but that the changes they describe are characteristic of gonorrheal salpingitis is denied. In these cases there is formation of pus even very early, though the earliest cases cannot be distinguished from the cases of laminaria salpingitis except by the presence of the gonococcus and the abundance of lymphocytes. In the pus there are abundant plasma cells and epithelium. Only later is the loss of epithelium and the formation of ulcers found. There is fibrin in the pus but no sign of necrosis.

The plasma cells, on which Schridde has laid so much emphasis, are found in the wall of the tube, in the projections of mucous membrane especially, and also in the pus. This picture is found frequently, and perhaps in every case of gonococcal infection of the tube, but it is found also in a few cases in which the clinical evidence is against gonorrhea and no gonococci are found. Waetjen noted five such cases so that he cannot agree with Schridde that the gonococcus is the exclusive cause of ulcerative processes in the tube with marked plasma cell infiltration.

tend the second for my daughter, and the third I reserve for my old age."

This generous offer was not, however, accepted by the King, perhaps on account of court etiquette, or perhaps a sudden change for the better in the royal finances.

On the 13th of February, 1820, the King's nephew, the Duke de Berry, was mortally wounded by the hand of an assassin. The following account of the tragedy is drawn from Dupuytren's own report to the Academy of Medicine, and Cabane's graphic description, which was based on this report.

The Duke was on his way back to the opera, after conducting the Duchess, who was a few months pregnant at this time, to her carriage. He had just turned to go back to the theatre, when the assassin, Louvel, plunged a poniard into his chest. The Duke cried out, "*Je suis assassiné, Caroline, un prétre!*" Unfortunately, the Duke pulled the poniard from his chest, and the wound started to bleed fast. The patient was carried to the ante-chamber of his opera box, and here Dupuytren saw him. Bleeding, then almost universally done, had been accomplished from the arm. There was a question that the poniard was poisoned, and Dr. Bougon heroically applied his lips to the wound; luckily for him, this proved not to be the case. After consultation, Dupuytren decided to enlarge the wound and see if he could not stop the hemorrhage, which was exsanguinating the Duke. This exploration showed a penetrating wound of the chest, and all the surgeons present felt that further intervention was not to be thought of, and that nothing more could be done. The King, who had been anxiously awaiting the result of the consultation, addressed Dupuytren thus, "*Superestne spes aliqua salutis?*" and when Dupuytren replied in the negative, the King raised his eyes to heaven, saying, "*Que la volonté de Dieu s'accomplisse.*" The autopsy showed that the poniard had passed through the right lung, the pericardium, and had entered the right auricle. There were two litres of blood in the right side of the chest.

Notwithstanding the King's gratitude to Dupuytren for his services in this sad case, his treatment was severely criticised by his confrères, and most of them argued that non-interference would have been a better policy. Nothing could, however, have changed the result.

It is of interest that Dupuytren was made the hero of one of Balzac's novels, under the name of Desplein; the novel was the "*Messe de l'Athée*," and Desplein (Dupuytren) is described thus: "Desplein, one of the greatest of French surgeons, appeared like a meteor in the world of science. . . . Like all geniuses, he was without an heir. . . . The glory of surgeons resembles that of actors, which exists only in their life, and their talent is not appreciated when they are gone."

Sainte-Beuve, Malgaigne tells us, often spoke with pride of the fact that he had had the honor of being at the Hotel Dieu as one of Dupuytren's externs.

The following incident well illustrates the great surgeon's insight into human character. When patients came into the clinic suffering with dislocations, it was the practice of some surgeons to have the patient made somewhat intoxicated, so that there could be more muscular relaxation obtained, and the dislocation reduced more easily, and without danger. Dupuytren used other ways, as will be seen. A woman came into the clinic with a dislocation of the shoulder. Said Dupuytren, "Your hurt comes from the fall you have had, but you didn't tell me you were drunk when you fell; your son told me." The woman fell in a sort of swoon at this, and Dupuytren reduced the dislocation in an instant. When the woman recovered consciousness, Dupuytren said to her, "Your shoulder is in place, and I know perfectly that you only drink water."

In 1822 Dupuytren operated on a young girl for the removal of a tumor of the neck. When the tumor was nearly ready for complete removal from the surrounding tissues, there was suddenly a hissing sound and the patient suddenly expired. Dupuytren, without moving, looked long and searchingly at the operation wound, and then explained to the onlookers what had happened, that entrance of air into a large cervical vein had killed the patient. This was the first time this phenomenon had been demonstrated. It is said he gave on the spot, sadly and gravely, as befitting the occasion, one of his most illuminating lessons.

Cruveilhier tells us that when things were going wrong at operations, and in great emergencies, where life hung in the balance, that "Dupuytren was more than a man, he was the god of surgery."

One of Dupuytren's sayings was, "I have been mistaken, but I have been mistaken less than other surgeons."

It is not to be wondered at that his almost superhuman efforts, long continued without rest, should at last have their effects, and one day while walking to the Hotel Dieu in November, 1833, Dupuytren was seized with an attack of apoplexy; it was a slight attack, and he continued on his way to the hospital, but the students noticed that his speech was thick, and soon after this, in 1834, he was obliged to take a respite from his labors. He returned, however, and his passage to the cemetery was a long and timed ovation. Before going to the cemetery he said, "La republique des sciences est morte." He was buried with a pomp and a funeral which attracted the greatest interest of the city. The cause of his own case, although it was never definitely ascertained, was probably a cerebral hemorrhage. He was a man of great scientific and literary attainments, and a man of great social and personal qualities. He was a man of great personal qualities. He was a man of great personal qualities.

him, wishing, as he said, "To take above the news of this world." He died on the 8th of February, 1835, at the age of 57, and it is said that over 1000 workmen assembled at his grave, to pay their last respects to the Surgeon of the Hotel Dieu. Two hundred thousand francs were left to medicine by Dupuytren, and this sum was used under the direction of Orfila, for the creation of a pathologic museum, which is known as the Musée Dupuytren in Paris.

Pilastre has the following words concerning this great man, which fittingly end an account of his life.

"Posterity has forgotten the faults and errors that the contemporaries of Dupuytren rigorously reproached him with, . . . and has confirmed the homage which science, far away from the passion of the times, has rendered to the greatest surgeon of the nineteenth century,—a man who had lifted himself from the most humble to the highest rank, and added another name to the glories of France."

## Medical Progress.

### PROGRESS IN GYNECOLOGY.

By STEPHEN RUSHMORE, M.D., BOSTON.

#### TRANSPLANTATION OF THE OVARY.

As a result of Tuffier's<sup>1</sup> wide experience in transplanting ovaries, he has formulated "a new theory of menstruation." It is, briefly, that each month there is produced by internal secretion in the body of the human female, a chemical substance of unknown origin. When a sufficient quantity has accumulated, it acts on the ovary, which in turn reacts, modifying the secretion. It is this modified secretion which produces menstruation and is eliminated with the menstrual discharge. If menstruation does not appear, the retained substance produces "autointoxication," known clinically as the change of life. Part of this theory, namely, that menstruation is a cleansing process, has a familiar sound.

One fact on which this theory is based is that Tuffier brought on menstruation by injecting blood serum from a patient who was just about to menstruate. Furthermore, menopausal symptoms disappeared following such injection. Tuffier holds, therefore, that menstruation should be preserved whenever possible in women under forty. He estimates that about one-third of the endometrium should be left instead of performing a complete hysterectomy. As ovarian tissue also is necessary, this need may be supplied by autoplasmic operation, successful in a large enough percentage of cases to make it

a justifiable procedure. The ovary or ovarian tissue is buried without suture in the subperitoneal fat of the abdominal wall.

That the success of such grafting is not enough for the relief of menopausal symptoms was shown by several cases in which regular monthly congestive periods were observed, presumably corresponding to ovulation, but without menstruation. Only when menstruation occurs are the menopausal symptoms relieved. It was this observation that led Tuffier to the conclusion that the suppression of menstruation was the real cause of the symptoms.

One of the practical problems suggested is the treatment of young women from whom it is necessary to remove both ovaries on account of disease which precludes reimplantation. Grafts from other individuals have always been failures in the hands of Tuffier though he is still hopeful that improved technique, namely, increased knowledge of the conditions under which tissue grows, may ultimately give success here.

The literature on transplantation of the ovary is reviewed to date by Martin<sup>2</sup> whose conclusions may be quoted as follows. The surgical value of the procedure is questionable and the results are disappointing. Autotransplantation of ovarian tissue as practised at present seems to retard and modify the symptoms of the artificial menopause in a certain number of cases. Probably the effect depends on the ability of the graft to maintain its vitality in its new environment. A simple technique seems to give as successful results in autotransplantation as does a complicated technique with an attempt definitely to couple up the blood vessels. The occasional success of homo- and hetero-transplants suggests that the antagonism of tissue, which is nearly constant, may be overcome, though just how is not known, and more successful results be obtained.

Storer<sup>3</sup> presents a discussion of the question of ovarian transplantation, based chiefly on a study of the literature, and reports a case in which the operation was apparently followed by a pregnancy. The patient had had the left ovary and both tubes removed three years before on account of gonorrheal infection. She was desirous of matrimony conditioned on the possibility of pregnancy, and demanded operation though success seemed improbable.

At operation there were many dense adhesions and the ovary was found to contain many small cysts. The tubal stumps were half an inch long. The right tubal stump was divided downward until the uterine cavity was laid open. The ovary was bisected from above downward so that each half retained at least some of its original blood supply. The cut surface of the distal half was closed with catgut and left in place. The proximal segment was introduced into the incision in the uterus and sutured so that most of the cortex projected into

cision was postponed, and the candidates required to go through more tests, and to deliver in public a thesis, the subject of which was not to be known until four hours before the public discourse. Dupuytren was successful, and it has been said that he had prior knowledge of the subject of the discourse to Roux. Judged from our study of Dupuytren's life, this does not seem probable; at all events, Roux later admitted that he was too young for the position at the time he tried for it. This occurrence was the starting point of a bitter feud between the two men, which was to last for many years. Later in life Dupuytren and Roux fell in love with the same young woman, and Dupuytren again carried off the prize.

In the year 1805, Dupuytren was attached to the service of Boyer at the Hotel Dieu, and he was claimed by the army to do his work as a conscript. He was, however, so much wanted at the hospital, that the Ecole de Médecine, at a special session of the faculty, pleaded an exemption for him which was granted. In 1808, he was appointed adjunt at the Hotel Dieu, under Pelletan, a surgeon of the old school, of somewhat *laissez faire* principles. Some of the most interesting and important events in Dupuytren's life occurred at this time, of which Malgaigne tells us in a most graphic way. A word concerning the Hotel Dieu, for which Dupuytren did so much, will be of interest, for here the great surgeon lived and worked almost constantly, for thirty years.

The Hotel Dieu was founded by nuns in 660 A.D., and has been in existence uninterruptedly ever since, 1256 years. For years it was a hospice for the poor and destitute, as well as the sick, and many of the poor of Paris found refuge there during the long, cold winters. The overcrowding, disease, and general misery were too frightful to be described. In the times of epidemics the very high mortality was greatly increased. Some things had been changed for the better before Dupuytren's time, but the mortality was still very high, and there was great overcrowding. Dupuytren changed all this and made order out of chaos. At this time there were 1000 beds, and fifteen wards, but five of these were surgical. There were 264 surgical beds, 191 for men and 73 for women. Dupuytren gave two of his wards to Breschet and Sanson, respectively, keeping 113 beds on his service. Fourteen hundred ward cases (surgical) were treated in 1829. In the old days five or six patients lay in one enormous bed or *charnier*.

Such was the Hotel Dieu, where Dupuytren's famous lectures were delivered, the wonderful "Legons Orales," which thrilled countless audiences.

Dupuytren worked with all his energy while under Pelletan, and, studying the ward cases with minute care, soon had his lazy chief at his mercy, regarding all questions of diagnosis and operative procedure. Malgaigne tells us that

Pelletan, as chief of the service, had the right to assist at all operations he gave his subordinate, and he, in turn, had the right to visit all patients in the ward, after his chief. Dupuytren would tear to shreds with merciless logic all the fanciful diagnoses of his chief in the presence of the students. He was in his turn mercilessly criticised, but his critics, conscious of his great ability, were obliged to find other things to complain of than his operative skill. Thus Percy named him the first of surgeons and the last of men, and Lisfranc, the "Brigand of the Hotel Dieu."

It so happened that Pelletan wished to have his nephew appointed in his place at the Hotel Dieu when the time came, instead of Dupuytren, and as Dupuytren's whole future at the Hotel Dieu was at stake, if this was done, we cannot perhaps blame him for his attitude towards the senior Pelletan if all is taken into account. How Dupuytren became chief of the Hotel Dieu was told to Malgaigne by Lisfranc, who was a former pupil, and later a rival of Dupuytren. The climax of the trouble between Pelletan and his junior was reached when a Russian officer was brought into the Hotel Dieu, for a deep wound of the thigh, received eight days before. Pelletan examined the case, thought there was a deep abscess, which had come to the surface above Poppard's, and made a quick, deep incision over the mass, when a fountain of blood gushed up, inundating the operator and his assistants. The femoral was cut across! Pelletan hesitated; Lisfranc, who was assisting, states that Dupuytren had told him how to deal with such a hemorrhage, and applying his fingers with firm pressure over the common iliac, the hemorrhage stopped. Pelletan, thinking it was the place itself he had wounded, and not being familiar with the ligature of large vessels, in common with many other surgeons of his time, made two parallel incisions above Poppard's ligament, passing a Deschamps' needle deeply between, then ligating the risses between, upon passing the abdominal wall as well as the deeper structures in the ligature, which he then tied tightly. He then asked Lisfranc to suspend the compression, which he reluctantly did. A few minutes hemorrhage showed that the vessel had not been included in the ligature, and despairing Pelletan crowded chloride of lime deep into the wound, but all to no purpose, as the hemorrhage continued. A fortunate officer was present, who, naturally caused much interest, and the Russian surgeon's recommendation was followed.

It was a very fortunate thing that the Russian surgeon was present, for the hemorrhage stopped, and the patient recovered. Pelletan was so much mortified by this, that he resigned his position as chief of the service.

Dupuytren was now chief of the service, and he was not long in making his mark. He soon had his ward cases under his eye, and he was not long in making his mark. He was not long in making his mark.

was appointed to this position on September 9, 1814, and two years before this he had been appointed professor of operative medicine.

It is of interest to note, particularly at this time, that in connection with his work at the Hotel Dieu, Dupuytren established a dressing station in the centre of the French lines during the revolution of 1830, and remained there all day under fire, with his interns, attending to the wounded. From 1802, the time of his first appointment at the Hotel Dieu, until 1835, he hardly missed a day, a period of over thirty years. Lenoire says, "We have seen him sick, febrile, icteric, accomplishing the rigorous duties which he had set himself, omitting nothing."

What manner of man was this king of surgeons and surgeon to the King? Probably no great man was ever more hated and envied, and at the same time more looked up to for his consummate skill. Gaillard tells us that he was of commanding figure; one could easily recognize the "grand maitre," a noble head and a forehead worthy of Jupiter Olympus. His words were usually brief; he had a tone of voice which had a finality about it which admitted of no discussion and no reply. His dress was of the simplest, and ordinarily he was negligent in this regard,—an old green coat, socks over the tops of his boots, he walked the wards of the hospital every inch a king, and woe be it to the person who thought they could presume, on account of his eccentric dress! He did not indulge in any luxuries, his whole mind and body being given to his work. It is said that he disliked compliments excessively, and the "flatteries which lay unction to the soul of the little great."

Pariset tells us that he criticised or blamed no one, which is probably untrue, as we know from studies of his early days at the Hotel Dieu. He certainly had reason in the "penible" beginnings to blame and criticize many. His expression was not, we are told, like the coldness of marble, but was somewhat preoccupied, giving the idea of one rapt in meditation. He would visit the hospital at six or thereabout each morning, and if all the house staff were not at attention, or any were missing from their proper place, there was trouble. He examined all the patients with great care, and laid great stress on a careful history, and repeated physical examinations. After the visit he would sit down on his big green sofa, which his assistants and students loved as part of himself, and talk over the cases. There was a special house-officer, whose business it was to make a *careful and minute record of all the unusual and interesting cases, the records of their operations, and to do nothing else.*

After the operations were over, and the cases in the wards had been visited, Dupuytren made it a rule to be present at any autopsy of a case in his wards, and he was the first surgeon to follow out this rule in France. "About eleven A.M., he took the little roll of bread given to the surgeons from time immemorial at the Hotel

Dieu, and without thinking anything about his old green coat with the holes at the elbows, walked along the pavements, munching his meagre crust." At this time, as Gaillard quotes, "*Nul autre à ses cotés live un front rival.*" Always at about seven in the evening he would make a second visit at the hospital to see the operated cases of the morning, and any others demanding attention. Dupuytren's private practice was slowly acquired, but at the zenith of his powers reached immense proportions. It is estimated that at this time he saw ten thousand patients yearly, outside his hospital work. With all this immense amount of labor, Dupuytren did not write as much as some of the other great French surgeons of his time, but what he did write was of the best. Much of this is contained in the "*Leçons Orales*," which were gathered in book form, and published by his pupils, Pierre de Boismont and Marks. Among the most interesting of these lectures to us today are perhaps the ones on bone cysts, abscess of the right iliac fossa, including appendicitis, and congenital dislocation of the hip. In the essay on bone cysts we find much that sounds as if it were written today, so clear is the knowledge of the condition, bone cyst occurring in the long bones, etc. Warning is given that bone cysts are liable to become malignant, and complete extirpation is advised. Dupuytren made an extensive study of gunshot wounds, and also began a work on stone in the bladder, which was finished by Sanson and Beggin. Perhaps the only work he is universally remembered by to this day, is his memoir on contracture of the palmar fascia, and its operative cure. He made a study of tuberculosis, and anthrax, and made an exhaustive study of burns, making a new classification. He was the first surgeon to amputate the cervix of the uterus for cancer, and the first to devise a rational procedure for excision of the lower jaw. His operation for the establishment of an artificial anus was one of his greatest triumphs. His work on fractures, and especially fractures of the fibula and the lower end of the radius, is classic.

No sketch of Dupuytren would be complete without a brief account of his relation to the Court of France, and the part he played in the sad event of the assassination of the Duke de Berry.

In 1816, he was created a baron, and the Order of St. Michael was conferred upon him, and in 1820, he was made consulting surgeon to Louis XVIII, and on his death, in 1821, he was appointed surgeon to Charles X. At this time Dupuytren had acquired great wealth, and being cognizant of the condition of the Royal exchequer, sent the following note to the King.

"Sire: Grace in part to Your benefactions, I possess three millions; I offer you one. I in-

## PROSPECTIVE MEDICAL MEETINGS.

THE seventh annual meeting of the American Association for Study and Prevention of Infant Mortality will be held at Milwaukee, Wis., on October 19, 20 and 21, 1916, under the presidency of Dr. S. Max Hamill of Philadelphia. The subjects to be discussed at this meeting include federal, state and municipal governmental activities in relation to infant welfare; the care available for mothers and babies in rural communities; standards for infant welfare nursing; and morbidity and mortality in infants from measles and pertussis. The session on measles and pertussis will be held in conjunction with the Milwaukee County Medical Society. The work of the meeting will be divided between the sections on obstetrics, propaganda, pediatrics, vital and social statistics, public school education for the prevention of infant mortality, and rural communities and nursing and social work.

The annual business meeting will be held on October 20, at which will be presented the reports of affiliated societies through which the association is in touch with activities for the prevention of infant mortality in seventy-six cities representing twenty-eight states, the District of Columbia, Canada and the Philippine Islands. The Association was organized in November, 1909, following a conference held at Yale University by the American Academy of Medicine. Its objects are to study the causes of infant mortality, to awaken interest in the possibility of its reduction, to formulate plans for its prevention, and to act as a clearing-house for the collection and dissemination of information on these subjects. The headquarters of the Association were established at Baltimore in 1910. Its work is carried on by correspondence from the central office, by investigations and studies made by standing and special committees, by its annual meeting, and the publication of its transactions and by a traveling exhibit. It has over 150 affiliated organizations and 950 individual members.

Members of this Association who attend the meeting in Milwaukee, are invited also to attend the forty-fourth annual meeting of the American Public Health Association, under the presidency of Dr. John F. Anderson of New Brunswick, N. J., which will be held at Cincinnati, from October 24 to 27. The program of this meeting has been adopted as the official program of the annual municipal health officers' conference of Ohio. At the general sessions of this meeting there will be symposia on mental hygiene and public health nursing. There will also be meetings of the sections of public health administration, laboratory, vital statistics, sanitary engineering, sociology, and industrial hygiene. This Association was established in 1872, and its membership includes the health officers of the leading cities in the United States and Canada, the executive officers of many state and provincial departments of health, the leading officials of the United States and Canadian Government health services, and many bacteriologists, chemists, sanitary engineers and sociologists.

The seventh annual session of the United States Congress of Surgeons of North America will be held at Philadelphia during the week of October 23, 1916. An elaborate financial program has been arranged at the various hospitals of the city in accordance with the custom of the Congress. There will also be a conference of the

sions, at which papers will be presented. The presidential meeting will be held on Monday evening, October 23, at which Dr. Fred Bates Lund, of Boston, will be inaugurated and will deliver the presidential address on "The Indications of Cholecystectomy." There will be other papers on gall-bladder surgery, by Dr. J. M. T. Finney of Baltimore and Dr. Charles H. Mayo, of Rochester, Minn. The evening session of Tuesday, October 24, will be devoted to renal and vesical surgery, and that of October 25 to gynecology and obstetrics. On these days, also, there will be a special symposium on ophthalmic, rhinological and laryngological surgery. On Thursday evening, October 26, there will be papers by Dr. C. A. Porter of Boston on "Surgery of the Peripheral Nerves," and by other surgeons of distinction on various aspects of the cancer problem. On Friday evening, October 27, a public meeting will be held under the combined auspices of the Philadelphia County Medical Society, the department of public health and charities, and the Clinical Congress of Surgeons of North America. At this meeting Dr. Weston A. Price of Cleveland will speak on care of the teeth, Dr. Joseph C. Bloodgood of Baltimore on diagnosis of cancer, and Dr. Robert W. Lovett of Boston on curable deformities and the importance of their proper treatment.

It is expected that the limit of attendance for this Philadelphia meeting will be reached some weeks in advance of its opening, so that those surgeons who wish to attend but have not yet registered are urged to apply to the secretary-general, Dr. Franklin H. Martin of Chicago. The Clinical Congress of Surgeons of North America has become an established factor in the surgical life of this country, and this annual meeting for 1916 promises to prove as attractive and valuable as its predecessors have been. It is a matter of local congratulation that this Congress is to be held under the presidency of a Boston surgeon, to whom the JOURNAL takes pleasure in extending its good wishes for his tenure of this honorable and distinguished position.

#### A PSYCHIATRIC CLINIC FOR PRISONERS.

THE establishment of a psychiatric clinic by the Rockefeller Foundation in Sing Sing prison marks a long step forward in dealing with this

class of offenders against society. Every one is familiar with the work done by Warden Osborne and his Mutual Welfare Society, but now we are approaching the problem from another, more scientific, side. Whether the results will be as encouraging or not remains to be seen. Certainly the work would seem to be directed against the very nucleus of the problem,—the mental make-up of the criminal, which led him to crime, the possibility of a readjustment of his attitude towards life, and the therapeutic indications for cure.

The actual work of the clinic began August first, under the direction of Dr. Bernard Glueck, formerly of the Government Hospital for the Insane, where he had been for six years in charge of the Howard Hall Department, where are sent all federal prisoners who become insane. Glueck has already contributed largely to the literature of insanity among criminals, and is the author of a work, "Studies in Forensic Psychiatry," which is now in the press. He is one of the American exponents of Alfred Adler, and it will be interesting to observe whether or not his studies of neuroses among prisoners will bear out Adler's views of organ-inferiority rather than Freud's sexual etiology or Jung's libido concept.

It is high time, indeed, that some effort was made in this country to investigate the mental status of the habitual criminal, especially the vagabond type of Kraepelin. It will surprise no one who has had any acquaintance with psychiatry to find that a large percentage of these individuals are defective in some way,—high-grade imbeciles, psychopathic characters, constitutional inferiors, or abortive precoces.

The most important part of the work of the new clinic, however, will be the determination of the future of such cases. Many solutions have, of course, been offered in the past. Sterilization, reëducation and permanent segregation are the three chief. Without taking the space here to discuss the matter more fully, it is probable that the most satisfactory disposal of the State's habitual criminal would be the establishment of a colony where they could be definitely separated from society as a whole for an indeterminate time, possibly for their lifetime. However, we shall see what the new clinic has to offer along this line. Certainly we may expect from Dr. Glueck a comprehensive study of the subject and illuminating contributions to its literature.

fifth, was very anxious that the possibility of conception should not be removed, though she realized the danger to herself. The operation which Stoeckel performed was to make incisions as for the Alexander-Adams' suspension of the uterus, opening the peritoneal cavity, however. The tube was then drawn up and buried for its outer one-half beneath the peritoneum. By using fine catgut in the serosa only of the tube and employing great care, there was almost no trauma to the tube. The result so far has been entirely satisfactory. Whether the tubes will later be opened and whether then conception will occur, cannot be told, but the operation would seem to offer a possible method of inducing temporary sterility.

## Book Reviews.

### *The Kinetic Drive, Its Phenomena and Control.*

By GEORGE W. CRILE, M.D., Professor of Surgery, Western Reserve University, Philadelphia and London: W. B. Saunders Co. 1916.

This small volume presents the text of the Wesley M. Carpenter Lecture delivered by the author before the New York Academy of Medicine in 1915. It is a preliminary epitome of a projected monograph which will offer complete experimental evidence upon which the themes and postulates of this essay are founded.

By kinetic drive Dr. Crile indicates the state of increased energy transformation characteristic of modern human civilized life. This increased activation is secured by the kinetic mechanism of the adrenals and the thyroid. As kinetic diseases the author describes Graves' disease, cardio-vascular disease, Bright's disease and diabetes. He differentiates between acute and chronic emotional activation by means of the kinetic drive and outlines the means of its medical and surgical control. The operative

treatment of these kinetic diseases he describes briefly as dekineticization. The work is illustrated with a series of twenty-one excellent figures, many of which are full-page plates. It is an admirable and interesting preliminary statement of a new development of the author's now familiar theory of nociceptor stimulation. The publication of the completed work will be awaited with attention.

### *Diseases of Occupation and Vocational Hygiene.*

Edited by GEORGE M. KOVER, M.D., LL.D., Washington, D. C., and WILLIAM C. HANSON, M.D., Belmont, Mass. Philadelphia: P. Blakiston's Son & Company, 1916.

This volume, edited by two well known industrialists and sanitarians, presents the contributions of 29 selected experts on various aspects of industrial diseases and the hygiene of vocation. The work is prefaced by a historical review, by the editor, of the development of industrial hygiene and of its progress in the United States. The text of the book is divided into three parts, of which the first deals with specific and systemic diseases of occupation, with fatigue and the neuroses; the second with the causation and prevention of the diseases and accidents of occupation; and the third with the methods of investigation employed in the study and control of industrial conditions from the hygienist's standpoint. The book is illustrated with 46 cuts and a number of reference pages. Particular attention is directed to the chapters on diseases and hygiene of the ear, skin and nervous system and on those relating to carcinoma and the diseases of animals important in industrial connection. The volume should establish its value as a standard textbook of these subjects of new and growing popular and professional concern.

*Diagnostic Methods.* By HERBERT THOMAS BROOKS, A.B., M.D., Professor of Pathology, University of Tennessee. Third edition. St. Louis: C. V. Mosby Co. 1916.

This third edition of Brooks' laboratory manual of clinical chemistry, appearing so long at a time after the publication of its predecessor, is evidence that the book has proved itself among many similar works. It is intended as a guide for history taking, recording, and routine physical examinations and the laboratory tests necessary for studies in clinical pathology, for hospital use, and for consulting physicians. It is written for those who have only a limited knowledge of chemistry, to give to laboratory workers a guide which has been carefully revised from time to time, as obsolete tests have been discarded and new ones added, and there is a complete chapter on the topic of staining and examination of smears and slides. The book is illustrated with 100 figures.

*The Physiology of the New-Born Infant. Character and Amount of the Katabolism.* By FRANCIS G. BENEDICT, M.D., AND FRITZ B. TALBOT, M.D., Carnegie Institution of Washington. Publication No. 233.

This contribution from the Nutrition Laboratory is a report of one phase of the study of new-born infants by Drs. Benedict and Talbot, that has been going on for several years, and of which other phases have been reported in other places. This report shows that the view so generally prevalent of a large storage of carbohydrate in the human embryo, is probably not altogether in accord with the facts, although it appears that the metabolism is more nearly of the carbohydrate type the sooner after birth the determinations are made. These authorities show clearly that it is only a matter of a few hours before whatever reserve of carbohydrate may have been present is exhausted, and the infant is thrown upon its tissues (chiefly fat) for its energy supply. In the light of this fact they discuss the question of proper dietetic treatment of the new-born. They show that colostrum, although admirable in substance, is not sufficient in amount to serve the full requirements of the young infant. They suggest, moreover, that since the early metabolism is not carbohydrate, as has been supposed, there is a possible danger of acidosis if the metabolism is over-accentuated. The importance of preventing undue muscular exertion on the part of the new-born infant, as in excessive crying, is shown, and the possibilities of artificial nourishment at this period discussed. The report is well worth the careful attention of pediatricists and others who are interested in the problems of infant nutrition.

*A Manual of Gynecology and Pelvic Surgery for Students and Practitioners.* By ROLAND E. SKEEL, A.M., M.S., M.D., Associate Clinical Professor of Gynecology, Medical School of Western Reserve University; Visiting Surgeon and Gynecologist to St. Luke's Hospital, Cleveland; Fellow of American Association of Obstetricians and Gynecologists; Fellow of American College of Surgeons. With 289 illustrations. Philadelphia: P. Blakiston's Son & Co. 1916.

"This manual is intended to furnish a concise, practical working knowledge of gynecology with especial emphasis upon diagnosis and treatment." The intention of the author has been carried out well along established lines. The text is much better than the illustrations, which need more completely descriptive legends to enable them to fulfill their purpose. The lists of references to the literature are a feature which

other American textbooks of gynecology would be wise to adopt. They are not intended to be complete, but they serve to indicate quickly where further treatment of a subject may be found. There are a few typographical errors which might be misleading, as the legend below Figure 266. In general the book is quite up-to-date and its estimates of recent innovations are just. In its field, the book should prove a distinctly useful addition to the works on gynecology.

*Progressive Medicine.* Vol. xix. No. 2, June 1, 1916. Edited by HOBART AMORY HARE, M.D., assisted by LEIGHTON F. APPLEMAN, M.D. Philadelphia and New York: Lea & Febiger.

This number of *Progressive Medicine* presents the usual digest of progress in medical and surgical sciences during the preceding quarter. Under the subject of "Hernia," particular attention is devoted to the relation of this condition to the Workmen's Compensation Law. Surgery of the abdomen and gynecology are separately considered. Under the latter, Percy's heat method in the treatment of inoperable uterine carcinoma is discussed in detail and illustrated by several figures. Under "diseases of the blood" are considered diathetic and metabolic diseases, diseases of the thyroid gland, spleen, nutrition and lymphatic system. There is a brief terminal section on ophthalmology. The volume is a valuable contribution by a score of well-known American experts to the literary record of recent progress in the medical and surgical sciences.

*The Practitioner's Medical Dictionary.* By GEORGE M. GOULD, A.M., M.D. Third edition revised and enlarged, by R. J. E. SCOTT, M.A., B.C.L., M.D. Philadelphia: P. Blakiston's Son & Co. 1916.

The two previous editions of Gould's Medical Dictionary have been reviewed in former issues of the JOURNAL with approval. This third edition, based on recent medical literature and containing all the words and phrases generally used in medicine and allied sciences, with their pronunciation, derivation and definition, is issued to bring the publication to date by the inclusion of new and current words and terms, and of words from the sciences allied to medicine. About 20,000 such new terms have been added making a total of over 70,000 words in the dictionary. The work is illustrated with many tables and a few cuts. The author and the editor are to be commended for retaining the Greek letters in their etymologic descriptions. The book should continue to fill its useful and established position as a reliable and complete medical dictionary.

of urine, due to a multitude of individual causes; then causes which lower the vitality of the body in general and of the bladder in particular, as depressing illness, toxemias, exposure to cold. Probably the greater mobility of the right kidney explains the increased frequency of infection found there.

The exciting causes are bacteria, coming from infectious foci anywhere in the body, especially if in or near the intestinal tract. It seems as though the bacteria from these foci originate the urinary disease and the colon bacillus is a secondary invader. Perhaps the answer to the first question is that they are not susceptible except when infected by some other organism first.

The weight of opinion at present is that these urinary infections are chiefly hematogenous in origin; some are due to lymphatic extension and a few are examples of ascending infection.

The natural course of these infections is short and acute, from five to twelve days. They tend to recovery unless there is persistence of some predisposing or exciting cause. This should be kept in mind and such cause or causes looked for and removed. Especially is this true in cases of relapse or chronic infection. If the course is chronic there is a tendency to suppuration of the kidney, or gradual destruction of the renal function.

The most satisfactory treatment in the acute stage is keeping the patient in bed, administering large quantities of water with urotropin and the application of heat to the lumbar region. When the acute symptoms have subsided, Furriss finds autogenous vaccines of benefit. Pyelitis, if persistent is treated with weak solutions of silver nitrate, but in every case a most careful search must be made for the cause of the trouble. This and the amount of damage already done to the kidney determine the treatment and whether operation is or is not indicated.

#### CALCIUM IN PELVIC DISEASE.

Of late years so much attention has been devoted to the operative treatment of various forms of disease, that too often the non-operative treatment has been neglected, and it is the non-operative treatment of inflammation in the pelvis that Landsberg<sup>21</sup> recommends. In this condition it is no longer considered good surgery to subject every case to operation, and there is considerable evidence as to the value of non-operative treatment, certainly in the acute stage.

Calcium has been found to be of value in combating inflammatory processes, and for about a year Landsberg has used calcium lactate in the treatment of acute pelvic inflammatory disease. The number of cases (eighteen) is too small to form a basis for far reaching conclusions. But under the administration of calcium the progress seemed more rapid than under other methods of treatment, which were

tried first. Calcium is now used in connection with other means of relief and employed in the form of a one per cent. solution, which is injected hypodermically. Not more than three cubic centimeters should be introduced at any one point, as it may cause marked skin reaction. The total maximum dose should never exceed ten cubic centimeters. The injections are repeated every two or three days, as near as possible to the inflamed area. For vaginitis a five per cent. solution is recommended.

Another condition of which the treatment is discussed by Landsberg is the bleeding of puberty as well as of the climacteric, without obvious cause. There may be supposed some "dysfunction" of the ovary or of the uterus to account for it. Landsberg has employed extract of corpus luteum, prepared for hypodermic injection. The seven cases treated were cured, using one cubic centimeter of the preparation every two days, and observation for months afterward showed that the effect was not transitory.

#### GYNECOLOGICAL AFFECTIONS AND TUBERCULOUS DISEASE.

Butner<sup>22</sup> calls attention to the importance of making a thorough general examination in patients who complain of pelvic symptoms, but in whom there is little or no anatomical basis for such symptoms. In these obscure cases, of which he cites several examples, he has found, usually after he had been treating the patient for some time for pelvic disease, that the pelvic symptoms were due to tuberculosis of the lungs. It is this particularly which should be kept in mind in any obscure pelvic condition characterized by physiological rather than by anatomical abnormalities.

#### GYNECOLOGICAL DISEASE IN THE INSANE.

Gibson<sup>23</sup> reports a series of one hundred operations for gynecological disease in the insane. The question of the advisability of operations for the relief of gynecological conditions has received considerable attention of late, with some polemical discussion as a result of Bossi's contributions to the literature, but not many writers have attacked the subject systematically. The reports of series of cases have in general been of little value, for no effort has been made to classify the psychoses found. This is probably due to the fact that the operators are not familiar with psychiatry and depend on his associates to select and tabulate his cases.

Gibson has arbitrarily divided the various forms of insanity into two groups. 1. Forms in which there appear various degrees of deterioration or dementia, and 2. Forms in which dementia does not appear. For the first group of cases there is little to be gained by operation, except that it may improve the physical condition, and make it easier to care for the patient. In the second group of cases the re-

sults of operation may be beneficial, for if definite lesions were corrected it may be thought that some effect on the psychosis can be determined. To prove this will take long series of cases, and the patient observation over long periods of time. Immediate results are not conclusive.

The immediate results in a series of one hundred cases are reported by Gibson, however, the mental condition of the patients being determined by the staff of the Kings Park State Hospital. Of these, fifty-five belonged to the first group in which no benefit was to be expected and none was actually found. Seventeen of the second group were considered by the staff to be benefited by the operation. Of twenty-six of the manic depressive group, thirteen were improved, or fifty per cent. But, of course, a long period of observation is necessary to determine permanent results. The operative mortality was one per cent., death resulting from a pontine hemorrhage the day after operation.

The earlier investigators gave a large percentage of improvement, some even as high as sixty-eight, while later writers give from sixteen to eighteen per cent. The author agrees with Tauszig's conclusions that every woman with manic depressive insanity should have a pelvic examination, and if a definite lesion is found, it should be corrected by local treatment or operative measures.

#### NERVOUS PHENOMENA FOLLOWING OÖPHORECTOMY.

Gordon<sup>24</sup> has seen so many ill-advised operations on the female genitalia, that he presents a summary of some of his experiences. If the ovaries are removed the effects are far reaching and multiform, as can be seen by the changes which take place in the other glands of internal secretion. The equilibrium of the system is upset and there arise distinct disturbances, chiefly functional. It is the nervous and mental disturbances which Gordon considers especially in his paper.

The series covers one hundred and twelve cases, in thirty-seven of which oöphorectomies were performed through errors in diagnosis. In thirty-four women who complained of various manifestations of neurasthenia, psychasthenia or hysteria, there was complaint, among other symptoms, of vague disturbance in the abdomen. Oöphorectomy was advised and was carried out. The organs were found to be normal, but the immediate effect of the operation was beneficial in some, yet without effect in others. Later the symptoms became worse in all.

In the remaining seventy-five cases, there was some disease of the pelvic organs; radical operations having been advised and accepted were performed. While operation removed some local symptoms, others more severe with mental and nervous disturbances developed in the months following operation. Some of the patients, though not actually insane, required care in an institution.

Gordon urges that, since the removal of the reproductive organs produces such profound mental and nervous symptoms, they be not removed for slight cause or for no cause at all, as in some of the cases he saw. A more thorough study of the patients who complain of nervous symptoms or of pains of a vague character should be made by a neurologist before the operation is decided upon.

#### COAGULEN IN PELVIC SURGERY.

Albrecht<sup>25</sup> encouraged by the favorable results of the use of coagulen reported by Fonio, Kocher and others, has employed it in gynecological conditions. Coagulen is a substance which hastens the coagulation of the blood; it was prepared by Fonio from animal blood platelets, and has been placed on the market by a Swiss firm. Its effect is described by Fonio as hastening and increasing the coagulation of the blood. This is very marked in the test tube, but if given subcutaneously or intravenously, it produces quickly a transitory shortening of the coagulation time of the circulating blood.

The trade form is a powder, but a ten per cent. solution should always be freshly prepared for administration. The cloudy solution may be boiled for two or three minutes without impairment of its action. The bleeding surface is sponged off and immediately a pack wet with the solution is applied.

Albrecht's experience may be summarized briefly. Coagulen works promptly in parenchymatous oozing from raw surfaces. In arterial bleeding and in any considerable venous bleeding, it is of no value, for the blood pressure quickly displaces any clots which may form. The field in gynecology and abdominal surgery is thus chiefly intraperitoneal, in oozing from raw surfaces in the pelvis or on the intestine. If the pack is removed with care, no bleeding occurs, and no post-operative bleeding has been reported.

A substance which checks bleeding so satisfactorily has been used, of course, for many hemorrhagic conditions, for example, in the essential menorrhagia in young girls, where it was given hypodermically (quite painful). But after twelve hours there is no appreciable effect on the blood. Intravenous injection has been followed by collapse in several instances and may be regarded as too dangerous. In melena neonatorum as in hemophilia, its use has been followed by the desired result. But in abdominal and pelvic surgery, it is a certain and rapid local styptic in parenchymatous bleeding from raw surfaces.

#### FACULTATIVE STERILITY.

Stoeckel<sup>26</sup> has practised a new method of operating to produce "facultative sterility." His patient who had had five children in five years, with a psychosis in the fourth pregnancy which appeared again in a more serious form in the

in this way, but no harm is done by this treatment.

(2) Making vaginitis in children a reportable disease, as the disease nearly always comes from outside the family and the patient is innocent.

(3) Instruction of parents of infected children—through the visiting nurse—regarding preventive measures to limit infection.

(4) Investigation by the visiting nurse as to the probable origin of the infection with a view to preventing contamination of other children.

(5) Adoption of the U-shaped seat with the low bowl and other precautionary measures to prevent spread of infection through public lavatories in schools, play grounds, comfort stations and tenements.

"Gonorrhea in adults is so intimately connected with the public morals that any marked diminution in its presence seems like trying to reform the universe. Gonorrhea in little girls, on the other hand, is simply the result of inadequate sanitary precautions . . . a disgrace to the hygienic methods in the beginning of the twentieth century."

#### VAGINITIS.

Hoehne<sup>13</sup> attributes to the activity of the *Trichomonas vaginalis* a characteristic form of vaginitis. The parasite has already been recognized as an inhabitant of the vagina, and in association sometimes with inflammation, but generally it has been considered as of no pathogenic significance. Hoehne reports a series of twelve cases which he selects from a series of over a hundred, in which he found abundant masses of the infusoria, varying forms of bacteria, but no gonococci. The discharge was rather thin, abundant, yellowish and foamy, irritating and causing marked inflammatory reaction, occasionally ulcers. Subjectively the symptoms vary but were chiefly burning and itching, sometimes so severe as to interfere with patient's occupation.

In a series of one hundred and four non-pregnant women, the parasites were found twenty-nine times, and in a series of one hundred and two pregnant women, thirty-five times. That is, in nearly one-third of the cases examined, the trichomonas was present, never with the gonococcus, though often with other bacteria. He describes at length the technique employed in fixing and staining the parasites, but defers until a later paper a discussion of the therapeutic measures which he has found so successful.

#### VAGINAL BACTERIA AND MENSTRUATION.

Hellmuth<sup>14</sup> has conducted a series of investigations to determine, if possible, whether menstruation has any influence on the hemolytic properties of the bacteria in the vagina.

It is very unusual to find hemolytic streptococci in the vagina during pregnancy, but they are not infrequent in the lochia even in patients who have no elevation of temperature. The significance of the hemolytic property is not at all understood. By some it is regarded as a definite characteristic property, especially in the virulent strains of streptococcus. By others it is thought that hemolysis has nothing to do with virulence, but is simply due to the blood content of the nutrient medium and is, therefore, a purely accidental peculiarity which the different bacteria causing puerperal fever assume under certain as yet unknown conditions. If the presence of blood in the medium is then a determining factor, hemolysis would be expected in continued bleeding as in prolonged menstruation or in menorrhagia.

Hellmuth investigated carefully in both in- and out-patient departments of the clinic, under very rigid precautions, to prevent contaminations. In three cases out of thirteen, there were found hemolytic bacteria, one in- and two out-patients. The in-patient had a purulent abdominal incision and hemolytic bacteria were found on the external genitalia as well as in the vagina. The two out-patients could not be controlled, of course, and the germs may have been introduced at coitus. But in twenty-two examinations during and in the first three days following menstruation, there was no trace of hemolytic bacteria. This indicates that it is not the blood content of the medium which is the cause of the hemolytic property of bacteria.

#### DYSTOCIA FOLLOWING PERINEORRHAPHY.

Pouliot<sup>15</sup> reports a case of dystocia due to suture of the levatores ani. The patient had had a forceps delivery and six months later underwent an operation for repair of the torn perineum. During the ensuing pregnancy the attending physician was struck by the thickness and firmness of the perineal body which at the time of labor proved too resistant for the normal expulsive forces, and "episiotomy" had to be performed. This result of perineoplasty, not very rare if suture of the levators is undertaken, should be carefully guarded against in young women who are likely to have children. "To wish to do better than Nature may be dangerous," and if the levators are approximated, their line of contact should be as nature provides.

#### COMPLETE TEAR OF THE PERINEUM.

Pozzilli<sup>16</sup> describes in minute detail a new operation for complete laceration of the perineum which he has practised for several years. The operation already described in outline. The first step is the operation of perineoplasty, consisting of freeing the rectum and levatores ani. An H-shaped incision is made, extending from the vagina and external labia to the perineal body laterally, to permit the removal of the perineal

very little traction, to the perineum or to the newly constructed anus. A flap is thus turned down over the anus and the structures laterally including the levators are approximated in the median line. The operation is not new, but the excellence of Pozzi's description and the clearness of the illustrations deserve attention.

#### LEUCORRHEA.

Zweifel<sup>17</sup> describes at some length the treatment of leucorrhœa. After reviewing a few of the older procedures, he calls particular attention to some of the more recent methods of treatment, mentioning the dry method, the use of yeast preparations, sugar and lactic acid. *Bolus alba* (kaolin) is introduced as a powder and gives immediate beneficial results, but soon after treatment ceases, there is a recurrence. Of the yeast preparations, Zweifel gives no description, as he has had no personal experience with them.

Following the suggestion of Kuhn, Zweifel has employed sugar in fifty per cent. solution, introduced on a tampon and left for twenty-four hours. The patient then uses a douche at night on going to bed. The patient is instructed to put two teaspoonfuls of sugar in the irrigator, and two teaspoonfuls of very hot water on the sugar. The solution is then cooled and introduced into the vagina, after which the patient goes to bed. The treatment is continued at home for eight or ten days after which the patient returns for consultation.

Of sixty-six cases so treated, two-thirds came back and these showed very satisfactory results. A few, however, were resistant, and formalin was applied to the cervical canal. In the cases still resistant, lactic acid in solution of one-half of one per cent. was employed. If this strength gives burning or irritation, it may be diluted. This general line of treatment gave satisfactory results, and as the patients were kept under observation for some time, the beneficial permanent effects were determined.

#### URINARY INCONTINENCE.

Newman<sup>18</sup> describes an operation for urinary incontinence due to incompetence of the sphincter of the bladder which he has devised, and has been using for a number of years. It resembles somewhat an operation described by Kelly, but differs from that in its main object. Newman uses a knobbed bougie in the bladder drawn against the internal meatus to determine the position of the neck of the bladder. He then makes a lozenge shaped denudation of the vaginal mucous membrane, an inch and a half or two inches in length with its widest part, about three-fourths of an inch, over the bulb of the bougie. The tissue is then approximated from side to side, with interrupted or Lembert mattress sutures, which push in the tissues lying in the median line. Over this the vaginal tissue is closed to give further support. New-

man says the object of the operation is to bunch up the mucous membrane inside the internal meatus, thus blocking the passage of the urine and giving control. Undoubtedly there is some shortening of the sphincter of the bladder also.

#### BLADDER FUNCTION AFTER CONFINEMENT.

The question of why catheterization is necessary in the puerperium and especially after operation, has not been answered satisfactorily for all cases. But certain factors seem clear, and Taussig<sup>19</sup> analyzes the histories of one hundred and fifty-seven puerperal, and four hundred and five post-operative (non-puerperal) cases. Among the interesting points which he brings out in his discussion are first, the influence of the form of anesthesia, comparing fifty-eight cases operated on under spinal anesthesia and fifty-eight cases operated on under ether, all voiding spontaneously. In the former group, ten and one-half hours was the average time for the first voiding, in the second group, twelve hours. It was noted also that some cases voided spontaneously, but were not able to empty the bladder, so that catheterization became necessary after several days.

Taussig favors the retention catheter for post-operative paralysis, (cancer of the cervix), but relies on the ordinary form of rubber catheter kept in place by adhesive plaster. Certain objections to the mushroom retention catheter are thus obviated.

In regard to infection, Taussig holds that the danger of infection lies less in the technique or frequency of catheterization, than in the presence of stagnating urine in the bladder. Therefore, prophylactic treatment should be continued until the bladder fully empties itself. As a harmless, but, under certain conditions, effective stimulant to the bladder Taussig has used air injected by means of an air tight syringe. In the few cases in which it has been used, it was successful ten out of eleven times. Other methods of stimulating the bladder have been recommended, of which pituitrin is sometimes efficacious and boroglyceride seems to do more harm than good, according to Taussig.

#### COLON INFECTION IN THE KIDNEY.

Furniss<sup>20</sup> discusses colon bacillus infections of the kidney and attempts to formulate answers to the following questions: (1) Why are the urinary organs so susceptible to the colon bacillus? (2) What are the factors predisposing to infection? (3) What is the exciting cause? (4) How does it gain entrance? (5) What is the natural course of the infection? (6) What offers the best means of eradicating the infection?

The answer to the first question is not easy. Furniss says "at no time have the urinary organs been the natural habitat of the colon bacillus." The predisposing factors are interference with function, from obstruction to the flow

## THE POSSIBILITY OF NOVOCAINE ADDICTION.

WHETHER or not the Harrison law will ultimately prove effectual in abolishing, or at least minimizing, the evils of addiction to drugs, is dubious as yet. The intent of the law is good, but recent judicial decisions and interpretations have warned us that there are vulnerable places in it. Leaving out of the discussion for the moment opium and its derivatives, we have to consider cocaine, which would present an easier problem. In the first place there is not in the case of cocaine an addiction in the special sense we mean when we speak of morphine addiction. The devotees of the former drug get in the habit of taking the drug at intervals, these being regulated, in the lower class of users, by fluctuations of their personal finances, and in the higher class by circumstances of expediency. Following a cocaine debauch there is a true depression, but not the physiological craving for the drug which the opium habitué experiences. In the second place, cocaine has a more limited field in medicine than opium does, and it is not impossible that it may be replaced as a local anesthetic by other drugs, which do not possess among their properties the production of emotional exaltation.

Among the drugs which naturally occur to us in this connection is novocaine. This powerful anesthetic, like others of its class, ends in "caine," to indicate its physiological action as a local anesthetic, but is not chemically related to cocaine, being the hydrochloride of the organic base para-amino-benzoyl-diethylamino-ethane, a derivative of para-amino-benzoic acid, while cocaine is benzoyl methyl-ecgonine. It does not appear, from what scant information is available, that novocaine produces the psychic effects which cocaine does; however, a great deal more data must be obtained before any conclusions can be drawn as to this. If true it would seem that the substitution of novocaine for cocaine, wherever at all possible, would be indicated, so that the latter drug could be withdrawn from the market entirely. Before this is done the proper procedure would be to test out novocaine on a group of individuals of varying temperaments, to see whether or not it ever produces emotional reactions of a pleasurable nature.

## PROGRESS OF POLIOMYELITIS EPIDEMICS.

DURING the past week the epidemics of poliomyelitis in the United States have continued, on the whole, with steady abatement. In New York City on September 30 the number of cases reached a total of 3029 with 2286 deaths. In New York State, outside New York City, on the same date, the total number of cases amounted to 2592 with 580 deaths.

In New Jersey the total number of cases on September 19 amounted to 3376, and in Illinois on September 16, 563.

In Massachusetts on September 30, the number of cases during that month reached a total of 608 as compared with 390 during the first eight months of the year. The largest number of cases has been 282 in Boston and the next largest in Holyoke, where, on September 30, there had been a total of 69 cases. On September 28 the number of cases in Pittsfield, Mass., reached a total of 42.

On September 26, Mr. Roger Pierce announced the formation of a Harvard Infantile Paralysis Commission to conduct research into the transmission and treatment of the disease, and to constitute a clearing house for the collection and free distribution of therapeutic blood serum. Mr. Pierce's statement is as follows:

"A Commission consisting of Dr. Robert W. Lovett (Chairman), Professor of Orthopedic Surgery; Dr. Milton J. Rosenau, Professor of Preventive Medicine and Hygiene; Dr. Francis W. Peabody, Assistant Professor of Medicine, and Roger Pierce (Secretary), has been appointed by the Harvard Medical School for the purpose of assisting in the early recognition, treatment and study of infantile paralysis.

The Commission has undertaken this work in the endeavor to meet the increasing demands from physicians for assistance in making an early diagnosis, and for serum to be used in the treatment of the earliest stages of the disease. It is not at present definitely established that the use of serum is of benefit in the treatment of the disease. In the opinion of some physicians it is; however, the results thus far obtained justify the distribution to physicians for use of the serum they deem it advisable.

The serum is obtained from the blood of persons who have recovered from the disease. The Commission, however, is not at present of the opinion that persons may be vaccinated with the serum. It is obtained by allowing the blood of persons who have recovered from the disease to be taken. The serum is then prepared by a process of filtration and is distributed to physicians for use. All persons who have recovered from the disease are eligible for the serum. The Commission is not at present of the opinion that persons may be vaccinated with the serum.

School (Administration Building), Huntington Avenue, and make inquiry for the Harvard Infantile Paralysis Commission. If this is not convenient, an expert will visit the home for the purpose of collecting the blood serum.

Physicians, by telephoning to the Harvard Medical School (Brookline 2380) and inquiring for the Infantile Paralysis Commission, may obtain an expert at any hour of the day or night, who will visit a patient with the doctor to assist in the diagnosis of the case, and to administer serum if desired. The amount of serum available will depend upon the response of recovered patients to this appeal for volunteers. As the response cannot now be accurately estimated, the efforts of the Commission will, at the beginning, be confined to cases in or near Boston. Should it be found possible to extend the service, every attempt will be made to do so.

There will be close coöperation with the State Department of Health and local health authorities.

The serum and all services rendered by the Commission will be free of charge."

Within the first forty-eight hours there were ten responses to this call for serum volunteers. The Boston theatres have now been closed to children, but the public schools were duly opened on October 2.

Attention has been directed to a study of epidemic poliomyelitis as it has occurred in recent years in Sweden. The first extensive outbreak of the disease in that country occurred in 1905, when there were about 1500 cases. About the same number of cases were scattered through the succeeding quinquennium. In 1911, occurred the most serious visitation of the disease in Sweden, where, during the next three years there were 10,000 cases out of a population of 6,000,000. This epidemic had a mortality of 19.79%, and of the survivors, 7000 were permanently disabled. Since 1913 poliomyelitis has remained endemic in Sweden. Wernstedt of Malmö, one of the leading Swedish authorities on poliomyelitis, working with Kling and Peterson, found that the secretions of the mucous membrane of the mouth contained virulent organisms of poliomyelitis 204 days after the onset of the disease. They, therefore, advise continued isolation of patients for a number of weeks after the disappearance of the acute symptoms. In the Swedish epidemics, maximum incidence of poliomyelitis has been at the age of two years.

## MEDICAL NOTES.

**IMPERIAL CANCER RESEARCH FUND.**—The fourteenth annual report of the Imperial Cancer Research Fund, under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England, has recently been issued, recording progress of the year ended July, 1916. The work of the laboratory, already restricted by the war, has, during the past year, lost the services of Dr. Tsurumi, who concluded his investigations on heterologous tumor immunity and left the laboratory at the end of October, 1915. The general conclusion which emerged from his investigations was that the hemolytic and hemagglutination reactions of the sera obtained by immunizing rabbits against mouse and rat tumors were those characteristic of the proteins of the mouse and rat. The complement fixation and precipitin reactions did not run parallel to the species serum reactions, but seemed rather to correspond to the histological characters of the growths used as antigens, showing a considerable independence of their origin.

**PREVALENCE OF MALARIA, PELLAGRA, SMALLPOX AND TYPHOID FEVER.**—The weekly report of the United States Public Health Service for September 15, 1916, states that during the month of July there were reported in Arkansas 810 cases of malaria, 75 of pellagra, 29 of smallpox, and 125 of typhoid fever. During the same period there were 133 cases of typhoid in West Virginia and 30 of smallpox in Colorado.

**CHOLERA IN JAPAN AND INDIA.**—The weekly bulletin of the United States Public Health Service for September 15, 1915, contains report of 1295 cases of Asiatic cholera in the Province of Anan, India, and of 353 cases at Osaka, Japan. There were 467 cases of bubonic plague at Rangoon, with 440 deaths.

**CHANGES IN COST OF DRUGS.**—Report from New York on September 20 describes various recent changes in the cost of drugs, chiefly in the direction of a reduced price for quinine and an increase in the cost of glycerin.

"Quinine has been reduced 10 cents an ounce by domestic manufacturers, who now quote 65 cents an ounce for bulk lots of the sulphate and 98 cents for the alkaloid. An irregular downward revision of all minor salts of quinine is also announced, cinchonine alkaloid being reduced to 25 cents and sulphate to 12 cents, while cinchonidine alkaloid was lowered to 95 cents, and this reduction came as a complete surprise to the drug trade, as manufacturers had long been holding the umbrella at 75 cents an ounce against an outside market price which has varied all the way from 60 to 75 cents an ounce. It is understood that the reduction in quinine was more or less in the nature of a speculative

two girls, weighing six pounds each, and a boy, weighing five pounds, twelve ounces. It is believed that this is the first instance of the delivery of triplets by this method. Official report of the case will be awaited with interest.

**RING SANATORIUM TRAINING SCHOOL.**—The annual graduation exercises of the Ring Sanatorium Training School were held recently at Arlington Heights, Mass. The principal address was delivered by Dr. E. W. Taylor of Boston. Other addresses were made by Dr. C. T. Warner of Marlboro and by Miss E. P. Davis of the State Board of Registration of Nurses. Diplomas were given to a class of thirteen pupil candidates.

**REDWOOD LIBRARY AND ATHENAEUM.**—The Committee appointed by the Directors of the Redwood Library and Athenaeum, of Newport, R. I., regarding the recent donation of books from the medical library of the late Dr. Rufus E. Darrah, would respectfully report:

That the thanks of the Library be gratefully returned to Mrs. Darrah for her gift of books from the medical library of her late husband;

That this contribution is the more to be appreciated, since the great change that medical literature and the practice of both medicine and surgery have undergone during the past half century has rendered the former works in this department chiefly useful as merely historical and as books of reference, while those of Dr. Darrah are alike of the recent time and in accordance with its advanced state of knowledge; and further,

That the Darrah gift is additionally to be valued from having been the companions and daily guides of a citizen of Newport who, besides his professional skill as a surgeon, was preëminent in his public relations to the city as educator and sanitarian, and ever zealous for the best welfare of Newport.

The Committee recommend that its report be formally adopted by the Directors, and that copies thereof be communicated to Mrs. Darrah, and through the lay and medical press to the many friends, in every field of life, of the late Dr. Darrah.

This report was presented at the special meeting of the Directors held on Tuesday, September 19, 1916, and was unanimously adopted.

ALFRED G. LANGLEY, *Secretary*.

## Miscellany.

### ANIMAL TRANSMISSION OF HUMAN DISEASES.

IN connection with the article by Dr. Mark Richardson in the issue of the JOURNAL for Sept. 21, suggesting the possibility of the transmission of poliomyelitis by the rat flea, it is of interest to note a paper read by Dr. David John David at the quarter centennial of the University of Chicago on June 6, 1916, and published in the issue of *Science* for September 8. This paper reviews and discusses certain relations of the lower animals to human disease, and conveniently tabulates as follows the diseases of man which are, or may be, transmitted by animals:

#### HUMAN DISEASES CARRIED.

##### 1. By the dog:

- Rabies.
- Foot and mouth disease.
- Helminthiasis.
- Fukes.
- Tapeworms (especially *Tania echinococcus*).
- Infantile splenomegaly (from dogs through fleas).
- Trypanosomiasis (*T. gambiense*).
- Mange.
- Fleas and ticks.
- Ringworm.
- Favus.

##### 2. By the cow:

- Tuberculosis.
- Actinomycosis.
- Anthrax.
- Cowpox.
- Tetanus (through vaccine).
- Foot and mouth disease.
- Septic sore throat.
- Rabies.
- Pus infections.
- Tenia saginata.
- Milk sickness.
- Paratyphoid fever.

##### 3. By the horse:

- Glanders.
- Rabies.
- Tetanus.
- Sporotrichosis.
- Anaphylaxis.
- Serum disease.
- Odor of horses.

##### 4. By swine:

- Trichiniasis.
- Tuberculosis.
- Anthrax.
- Cestodes (especially *T. solium*).
- Trematodes.

##### 5. By sheep:

- Anthrax.
- Tuberculosis.

##### 6. By goats:

- Malta fever.
- Tuberculosis.

##### 7. By the antelope:

- Sleeping sickness.

##### 8. By the cat:

- Rabies.
- Cestodes.
- Trematodes.
- Favus.
- Ringworm.

9. By rats:
  - Rat bite fever.
  - Bubonic plague (through fleas).
  - Trichiniasis (through hog to man).
10. By ground squirrels:
  - Bubonic plague.
11. By birds:
  - Psittacosis (from parrot).
12. By fish:
  - Tapeworms.
13. By arthropods, chiefly insects:
  - Mosquitoes:
    - Yellow fever.
    - Malarial fever.
    - Dengue fever.
    - Filariasis.
  - Fleas:
    - Bubonic plague.
    - Infantile splenomegaly.
  - Ticks and mites:
    - Rocky Mountain fever.
    - Relapsing fever (African).
    - Tick fever of Miana.
    - Japanese flood fever.
  - Lice:
    - Typhus fever.
    - Relapsing fever (*Spiracheta obermeieri*).
  - Bedbugs:
    - Kala azar.
  - Flies:
    - Sandfly fever.
    - Sleeping sickness (tse-tse fly).
    - Typhoid fever and other infections carried mechanically.
  - Crustaceans (water flea):
    - Guinea worm infection (dracunculosis).
  - Oysters, clams, etc.:
    - Typhoid fever.
  - Snails:
    - Trematode infections (especially bilharziosis).

The author further summarizes the methods by which infected agents may be transmitted through or by animals, and calls attention to certain points which may be of importance in the control of such diseases. The article is commended to the attention of physicians interested in the relation of animals to disease.

## UNITED STATES DEATH RATES IN 1915.

On September 19 the director of the Census Bureau of the United States Department of Commerce issued a preliminary statement of the population, deaths and death rates in the registration area of this country in 1915, with comparative rates for earlier years. This statement shows a total death rate in this area of 13.5 per thousand estimated population,—the lowest rate hitherto recorded in the United States. This rate was based on 909,155 deaths returned from 25 states (in one of which, North Carolina, only municipalities of 1000 population and over in 1910 were included), the District of Columbia, and 41 cities in non-registration states, the total population of this area in 1915 being estimated at 67,337,000, or 67.1% of the total estimated population of the United States.

"There is a widespread and increasing interest

throughout the country in respect to vital statistics. The states of North and South Carolina, which recently enacted the "model law" for the registration of births and deaths, were admitted to the death-registration area for 1916, increasing the estimated population of the area to 70.2% of the total for the United States in that year.

The death rate for 1915, 13.5 per 1000 population, is the lowest ever recorded, the most favorable year prior to 1915 having been 1914, for which the rate was 13.6. It is markedly lower than the average rate for the five-year period 1901 to 1905, which was 16.2. The decrease thus amounts to 16.7%, or almost exactly one-sixth, during a little more than a decade. When due allowance is made for the addition of many new states to the registration area between 1905 and 1915, and the comparison is confined to the group of registration states as constituted during the period 1901-05—the present population of which is about one-fourth of the total for the country—there is still shown a very considerable decrease, from 15.9 to 14.3 per 1000 population, or 10.1%. This decrease, on the basis of the present population, would amount to 42,876 deaths. On the assumption that a corresponding reduction has taken place through the entire country, this would indicate a saving of approximately 170,000 lives in 1915 for the United States as a whole.

The annual report for 1915, to be issued later, will state that changes in the age and sex constitution of the population must be considered before the exact nature and extent of the lower general mortality can be understood. It is certain, however, that the great progress made during recent years in the sciences of medicine and sanitation, together with the widespread awakening of the people throughout the United States to the support of public health authorities, has resulted in the saving annually of scores of thousands of lives that would have been lost under the conditions prevailing only a few years ago.

An accompanying table shows the death rates for the past three years separately and for the consecutive quinquennial years, 1901-1905 and 1906-1910.

The areas to which the figures relate are the registration states and the cities which had 100,000 or more inhabitants in 1910. Separate figures are given for the colored population in states in which colored persons constituted 10% or more of the total population in 1910, and in cities having 10,000 or more colored inhabitants in that year.

In the states for which death rates for 1901-1905 are given, the greatest proportional decrease between that period and 1915 is shown for Rhode Island, 16.9%. Next in order are New York, with a decrease of 14.6%; New Jersey, 14.3%; Massachusetts, 12.7%; Vermont, 9.3%; Connecticut, 5.1%; Indiana, 3.8%; New

Hampshire, 3%; and Maine, 1.9%. Michigan alone showed a slight increase, eight tenths of 1%.

Among the cities having 100,000 or more inhabitants in 1910 the tendency is toward a still greater reduction in mortality. The following-named cities show, for 1915, decreases of 20% or more, as compared with the 5-year period 1901-1915: Newark, N. J., 29.9%; Atlanta, 28.4%; New York City, 26.8%; Los Angeles, 25%; Jersey City, 24.9%; Pittsburgh, 23.9%; St. Louis, 22.9%; Denver, 22.7%; Providence, 22.3%; Paterson, 21.9%; San Francisco, 21.7%; Fall River, 21.7%; Louisville, 21.1%; and Nashville, 20%.

It should be borne in mind that the rates here given are "crude" rates, which make no allowance for differences in the sex and age distribution of the population, and that, furthermore, the rates for certain localities are materially affected by deaths of non-residents who are attracted to those localities by their favorable climate or by their superior hospital facilities. Inferences in regard to the relative healthfulness of different states and cities should not, therefore, be drawn without more thorough investigation.

#### THE STORY OF THE DAACK FAMILY: A STUDY IN DYSGENICS.

In a recently published bulletin (No. 15) of the Eugenics Record Office, Anna Wendt Finlayson, field worker of the Warren (Pa.) State Hospital, records, with a preface by Charles B. Davenport, a "study in hereditary lack of emotional control," based on the history of the Daack family in that State. As a study in dysgenics, this account suggests and deserves careful comparison with the well-known Jukes. The story of the Daack family has recently been summarized in the daily press from this bulletin as follows:—

"In 1815 William and Mary Daack and their young son, Samuel, came from Ireland and settled in Western Pennsylvania. William was a peculiar, silly old fellow who drank a good deal, stole sheep and other valuables. Mary, his wife and also his cousin, was ignorant, quarrelsome, and would become angry at her husband and leave him for days at a time.

"This pair proved a bad investment for the United States and particularly for Pennsylvania. Mrs. Finlayson, investigating for the Warren State Hospital, got track of 754 names of descendants or persons who married descendants. Taking out all persons dying at less than 20 years of age, all persons marrying into the family and all who moved away and were entirely lost track of, Mrs. Finlayson had left 153 descendants of William and Mary concerning

whom she was able to secure fairly complete data.

"Of the lot no one was a distinctly good citizen or a force for good in the community. Forty, although mostly of a low order of intelligence, are capable of controlling their emotions and have not been a burden on society.

"In the second group are 72 individuals. The members of this group show various evidences of degeneracy, such as shiftlessness, illiteracy, lack of average judgment, sexual irregularity, heavy drinking, quick and violent tempers and inability to control their emotions.

"In the third group are 41 individuals. Some of these have been in insane asylums, some in penitentiaries, some in jails, and some in poor-houses. Most of the insane have had some form of emotional insanity. They are quarrelsome, quick tempered, violent and given to sulking. The disposition to leave their marital mates is very marked.

"Twenty-five were insane, 20 are described as lazy and shiftless, 39 are below the average of intelligence and 34 are described as ugly and quarrelsome. Thirty were alcoholics, 27 were notoriously sexually irregular, 18 had a habit of leaving their husbands or wives, as the case was.

"Of the nine children of William and Mary, Jane and Curtis founded the two worst family trees. Jane married her cousin, a bad man. Curtis married a defective woman from defective stock. The traceable cost to the State for caring for worthless descendants of this pair is \$28,354. The actual cost to society has been infinitely greater than that. There is no way of knowing the cost to the State or the value to the State of the members of the family who have moved far away."

#### Society Report.

##### FIRST LEGISLATIVE CONVENTION OF MASSACHUSETTS PHYSICIANS.

Worcester, Mass., Sept. 20, 1916.

The convention was called to order at 11 a.m., by Dr. M. A. Tighe of Lowell, chairman of Middlesex North District Committee. As temporary chairman he reviewed the history of the movement to interest the medical men of the State in an effort to have the Workmen's Compensation Act amended so that it would be fairer to the physicians throughout the State.

He appointed as a Committee on Credentials: Dr. G. Forrest Marten of the Massachusetts Homeopathic Society.

Dr. S. A. Mahoney, of Hampden District.

Dr. J. A. Mehan, of Middlesex North District.

This committee, during a short recess, examined the credentials of those in attendance. After the recess the committee reported that forty men, representing fifteen of the district societies and the Massachusetts Homeopathic Society, were present. Report was accepted.

It was voted that officers of the convention consist

of chairman, vice-chairman, secretary and treasurer. Election was by ballot, and resulted as follows:

Chairman, Dr. William H. Merrill, of Essex North.  
Vice-Chairman, Dr. George O. Ward, of Worcester.  
Secretary, Dr. Joseph A. Mehan, of Middlesex North.

Treasurer, Dr. Ernest L. Hunt, of Worcester.

On motion of Dr. C. J. Burgess of Essex North it was voted that the name of the convention be, "The First Legislative Convention of Massachusetts Physicians."

It was moved by Dr. M. A. Tighe, of Middlesex North, that it is the sense of this convention that the Workmen's Compensation Act is unfair to the physicians of Massachusetts, and should be amended so as to give the injured workman the right to select his physician.

An amendment was offered by Dr. Mehan of Middlesex North, that the words "without sacrificing any of the benefits of the Act" be added.

Another amendment was offered by Dr. W. T. Hopkins of Essex South, that the words "workmen and" be inserted, so that the motion would read in part "unfair to the workmen and physicians."

A further amendment was offered by Dr. J. B. Howland of Suffolk that the words "or hospital" be inserted after the word physician so as to read in part "to select his physician or hospital."

The motion was freely discussed, and on motion tabled.

It was later voted to refer the motion as tabled to a committee of three, nominated from the floor, they to arrange a motion in accordance with the original and the amendments offered.

The Committee selected consisted of Drs. M. A. Tighe of Middlesex North, F. J. Cotton of Suffolk, and M. J. Cronin of Norfolk. They retired, and on returning presented the following resolution, which was unanimously adopted:

That it is the sense of this convention that the Workmen's Compensation Act is unfair to the workmen and physicians of Massachusetts, and should be amended so as to give the injured workman the right to select his physician, surgeon, hospital, or all three without sacrificing any of the benefits accruing to him under the Act. Furthermore, the Association should be responsible for the expense of medical and surgical and hospital care during the first two weeks after injury, and, if the employee is not immediately incapacitated thereby, from earning full wages, then from the time of such incapacity and in unusual cases—in the discretion of the board for a longer period.

The subject of health insurance was introduced by Dr. T. F. Greene of Norfolk and discussed by Drs. R. M. Merrick, F. J. Cotton and W. W. Walcott. The subject is of great importance to our men, but it was felt that we should not take a definite stand on the matter at this time because the convention had been called for the specific purpose of discussing the Workmen's Compensation Act.

Recess for lunch was taken from 1.30 to 2.15 p.m.

A motion was offered that the convention as organized be a permanent body. Following discussion, the motion was tabled.

It was voted on motion of Dr. I. J. Clark of Essex North that the organization of this convention and all of its actions be reported to the several societies for their endorsement or rejection, and that its permanency be entirely dependent upon their action.

On motion it was voted that when the convention adjourns it be to the call of the chair and officers.

It was voted on motion of Dr. F. B. Pierce of Essex North that a committee of one delegate from each district delegation and one from the Massachusetts Homeopathic Society be appointed and constitute a Central Committee, to be given full power to proceed in carrying out the recommendations of the convention.

It was also voted that each district delegation elect its member to the Central Committee, and a recess was taken for such election.

On motion of Dr. A. W. Marsh of Worcester it was voted that the quota of the Massachusetts Homeopathic Society on the Central Committee be three instead of one.

On motion of Dr. A. H. Quessey of Worcester North it was voted that the secretary of the convention be added to the Central Committee and act as its secretary.

The question of raising funds to carry on the work was discussed, and the method of raising them left to the Central Committee.

The Central Committee as elected is as follows:

Barnstable, J. P. Nickerson.

\*Berkshire

†Bristol North

\*Bristol South

Essex North, W. H. Merrill.

Essex South, W. T. Hopkins.

\*Franklin

Hampden, S. A. Mahoney.

Middlesex North, M. A. Tighe; J. A. Mehan, Sec.

Middlesex South, W. W. Walcott

\*Middlesex East

Norfolk, R. M. Merrick.

Norfolk South, N. S. Hunting.

\*Plymouth

Suffolk, R. M. Green.

Worcester North, A. H. Quessey.

Worcester, E. L. Hunt.

Mass. Homeopathic Soc., G. Forrest Marten, E. A. Fisher.

A rising vote of thanks was extended to the committee from Middlesex North "for taking the initiative in this work and organizing the convention."

It was voted that the treasurer of the Central Committee pay expenses incurred today by the convention.

At 4.20 o'clock it was voted to adjourn.

Sixty representatives were present during the convention. The greatest number of these present at any one time was fifty-one, and the least number at any time twenty-nine.

The above report is somewhat condensed, but is an accurate statement of the work of the convention.

Attest:

JOSEPH A. MEHAN,  
Secretary

#### CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE TWO WEEKS ENDING SEPTEMBER 23, 1916.

September 9.

P. A. Surgeon G. W. Shepard, to Receiving Ship, Norfolk, Va., Sept. 25, 1916.

Asst. Surgeon W. M. Drum, M.R.C., appointed from August 25, 1916.

P. A. Surgeon M. A. Stuart, to Navy Yard, Norfolk, Va., Sept. 25, 1916.

P. A. Surgeon J. A. Ballo, from N. Y. Recruiting Station, to Naval Hospital, Portsmouth, N. H.

Asst. Surgeon V. H. Carson, detached to Marine Expeditionary Force, San Domingo, to Cuba.

Asst. Surgeon J. T. Bonds, detached to Marine Hospital, Port-au-Prince, Haiti, to the Haitian Constabulary.

Asst. Surgeon J. B. H. to the Haitian Constabulary.

Surgeon J. C. Pryor, detached to the U. S. Marine and Surgery to Navy, Marine Hospital, Port-au-Prince, Haiti.

Surgeon I. N. Kelly, detached to the U. S. Marine Hospital, Port-au-Prince, Haiti.

Surgeon I. N. Kelly, detached to the U. S. Marine Hospital, Port-au-Prince, Haiti.

P. A. Surgeon John Buckley, commissioned from February 4, 1916.  
Asst. Surgeon J. C. Rushmore, commissioned from August 10, 1916.  
Asst. Surgeon Gordon Gibson, commissioned from August 10, 1916.  
Asst. Surgeon C. H. Francis, commissioned from August 10, 1916.

September 11.

Medical Inspector N. J. Blackwood, detached Navy Yard, Boston, Mass., to command *Solace*.  
Medical Inspector R. M. Kennedy, detached *Solace* to home, wait orders.  
Surgeon J. F. Leys, to Navy Yard, Boston, Mass.

September 13.

Surgeon Karl Ohnesorg, detached Asst. Naval Attaché, Berlin, Germany, to leave of absence.

September 18.

Medical Director J. D. Gatewood, detached command Naval Medical School, Washington, D. C., to Bureau of Medicine and Surgery, Navy Department.

Medical Director E. R. Stitt, to command Naval Medical School, Washington, D. C., September 25, 1916.

Medical Inspector R. M. Kennedy, to command Naval Hospital, Washington, D. C.

Acting Asst. Surgeon Dunn, to Marine Recruiting Station, Atlanta, Ga.

September 19.

Surgeon J. S. Taylor, detached *Alabama* to Force Surgeon Reserve Force, Atlantic Fleet, on *Rhode Island*.

Surgeon H. C. Curl, detached Force Surgeon, Atlantic Fleet, to Marine Barracks, Port Royal, S. C.

P. A. Surgeon G. B. Trible, to Naval Academy, Annapolis, Md., September 25, 1916.

September 20.

Surgeon H. F. Strine, to Naval Hospital and Medical School, Washington, D. C., September 25, 1916.

Surgeon R. W. Plummer, to the *Alabama*.

Surgeon G. F. Freeman, detached *Tacoma* to home, wait orders.

P. A. Surgeon H. A. May, detached Marine Barracks, Port Royal, S. C., to home and wait orders.

P. A. Surgeon P. E. Garrison, detached *Dolphin* to Expeditionary Force, San Domingo.

P. A. Surgeon E. H. H. Old, detached Naval Medical School, and Naval Hospital, Washington, D. C., to *Solace*.

P. A. Surgeon D. G. Sutton, from *Chester* to Naval Medical School.

P. A. Surgeon D. G. Allen, to the *Chester*.

The following Assistant Surgeons, M.R.C., have been ordered to the Naval Medical School, Washington, D. C., September 25, 1916, for course of instruction:

L. H. Williams, F. F. Murdock, O. D. King, A. C. Stinton, C. H. Francis, J. J. Laughlin, J. A. Halpin, E. E. Cox, A. W. Hoagland, A. M. Larsen, F. T. Weaver, I. W. Jacobs, A. H. Cechia, P. F. Prioleau, J. C. Brentley.

#### SOCIETY NOTICES.

THE MASSACHUSETTS THERAPEUTIC MASSAGE ASSOCIATION.—The next meeting will be held at the Hotel Brunswick, at 8.15 p.m., Thursday, October 12.

Dr. Hale Powers, assistant physician in nervous diseases at the Boston City Hospital, will address the Society on "Why Massage is Indicated in Epilepsy." Members of the medical profession invited.

DOUGLAS GRAHAM, M.D., President,  
Hotel Brunswick,  
MRS. MABEL F. WALKER, Secretary,  
115 Cedar Street, Malden, Mass.

NORFOLK SOUTH DISTRICT MEDICAL SOCIETY.—Meeting for Medical Improvement at United States Hotel, Boston, Thursday, October 5, 1916, at 11.30 A.M.

Reader: William H. Gilpatrick, D.M.D., of Boston.  
Subject: "Dental Radiography and Its Relation to Medicine." Illustrated with case histories. Stereopticon.

For Charles S. Adams, M.D., of Wollaston.

Other subjects which may be discussed are Physicians' Liability Insurance and "Workmen's Compensation Act." A full attendance desired.

F. H. MERRIAM, M.D., Secretary,  
South Braintree, Mass.

#### RECENT DEATHS.

DR. STEPHEN WENDELL ABBOTT died at a private hospital in Lawrence, September 1, 1916. He was a graduate of the Medical Department of New York University in 1879, joined the Massachusetts Medical Society in 1880, and had practised in Lawrence since that time, being retired from practice for several years. Formerly he was a member of the American Medical Association. He was for many years visiting physician to the Lawrence General Hospital and a member of the Lawrence Medical Club. He is survived by his widow, one daughter and one son.

DR. ENRIQUE NUÑEZ PALOMINA, secretary of sanitation in the national policies of the island of Cuba, and a prominent figure in public life, died at a hospital in New York, on September 15, after undergoing two operations for an infection resulting from a cut. His case was aggravated by diabetes.

Dr. Nuñez went to New York several weeks ago to investigate the methods being used to check the epidemic of infantile paralysis, because of the prevalence of that disease in Cuba, and also to visit curative springs in this country.

Dr. Nuñez was born at Madruga, Havana province, on January 16, 1872. He was graduated from the University of Havana in 1886, and as a surgeon in 1893. Afterward he became professor of medicine at the university. He was appointed secretary of public health on April 23, 1913, but resigned on June 15 of the same year.

Reappointed to the cabinet, he resigned again in 1914. Later, he reentered the Government service as secretary of sanitation and was considered an expert in sanitation and preventive medicine.

DR. EUGENE P. STONE, U.S.N., retired, who died recently at North Sutton, N. H., was a native of Boston. He was graduated from Harvard Medical School in the class of 1886, and entered the navy.

During his early life he saw considerable of army activities with his father, and had a part in the campaign against the Mute Indians. Dr. Stone served in Alaska for a long time, and at one time was attached to the President's yacht *Mayflower*. He was with the fleet which made the cruise around the world during the Roosevelt administration, and for some time was attached to the naval station at Annapolis. He was for two and one-half years in charge of the medical department at the Charlestown Navy Yard, but in 1911 was ordered to proceed to the Philippines to command the medical department of the navy there.

He was obliged to resign this post in a short time on account of failing health, and he then retired from the navy. He spent two years in Colorado, hoping to regain his health, and the past two winters he passed in Florida.

He is survived by his widow and by two sons.

WERE THE SAILORS OF COLUMBUS THE  
FIRST EUROPEAN SYPHILITICS?

By ANDREW F. DOWNING, M.D., CAMBRIDGE, MASS.

THE theory of the American origin of syphilis was first advanced four centuries ago. I use the term "theory" notwithstanding the opinions of those who are convinced that Iwan Bloch has given us conclusive proof. Today it is not unusual to read, in our medical journals, the unqualified statements of American physicians that syphilis was introduced into Europe by the returning sailors of Columbus; and even the laity are frequently heard to express the same opinion. From an American point of view, the discovery of this continent by the Italian, Christopher Columbus, is the most important as well as the most romantic event in the history of the world. Therefore, no American physician with a sense of pride or justice ought to be willing to admit, if it cannot be absolutely proved, that the price of the discovery of this new world in which he lives was that frightful epidemic of syphilis that devastated Europe during the last few years of the fifteenth and the beginning of the sixteenth centuries. To smear romance with the melancholy of venereal disease may delight the perverted mind of the unsentimental iconoclast; but to allow him to teach a rising generation, already wise in its knowledge of the social evil, to associate a loathsome disease with a great historic event, is to condone an unpardonable insult to the memory of Christopher C.

lunibus. It is the purpose of this paper to analyze, in the light of actual historical evidence, the principal arguments that are supposed to prove the American origin of syphilis.

To avoid confusion, all discussion of other theories is waived, and I shall consider the story of the beginning of syphilis only as it may or may not relate to the actual known facts of the discovery of America by Columbus.

On August 3, 1492, Columbus set sail from Palos, Spain, with three vessels and a crew of about ninety men. An alien with a Spanish crew, if we except an Irishman from Galway, a converted Jew, and an Englishman, he was facing a difficult task as he headed his ships into the "Sea of Darkness." His largest and only decked vessel was the Santa Maria, of about one hundred tons burden, the length of which has been estimated at from seventy-five to ninety feet. The two other vessels were the Pinta and the Niña, both undecked, the lengths of which have been estimated as fifty and forty feet, respectively. The crew of the Santa Maria, including Columbus and the officers, numbered about fifty-four men; that of the Pinta eighty, and the same was true of the Niña. On October 12, 1492, he landed on the island of San Salvador, and after a short stay there, he sailed around among the islands, eventually returning to his base, San Salvador, on October 28. On November 20 he was defeated by the Indians, and the command of the Pinta was given to the Niña. On December 6, 1492, Columbus returned to the mainland, the Niña, and the Santa Maria, and on January 1, 1493, the Santa Maria was wrecked at the foot of

Fiske remarks, "His armament was now reduced to the little undecked Niña alone, such a craft as we should deem about fit for a summer cruise in Long Island Sound."

For the purpose of reckoning a possible time of infection, it is important to notice the date of the arrival in Hayti, because this island is supposed to be the home of syphilis according to those who advance its American origin. It is probable, too, that the Pinta, before she again joined Columbus, spent most of her time here also, and therefore the approximate date of exposure of her crew would correspond to that of the crews of the other two vessels.

Having now only the little Niña, Columbus was obliged to leave at Hayti a colony of thirty-nine men, at a place called Navidad in honor of the Feast of the Nativity, on which day the Santa Maria was wrecked. This little group now falls out of our story, because, on his return about a year later, Columbus found them annihilated, murdered probably by the natives. They surely played no part in the origin of European syphilis. On January 4, 1493, he set sail for Spain, and two days later, on the northern coast of Hayti, came up with the Pinta, whose commander had been delayed trading with the natives and searching for gold.

In the two vessels there were about fifty men, exclusive of the ten Indians that were being carried back to Spain. From February 12 to 16, they encountered such a terrible storm in mid ocean that they gave themselves up for lost. During the storm, the vessels became separated, not to meet again until they were anchored in the harbor of Palos. "Those who have seen a gale of wind with a heavy sea in the latitude of the Azores," says Clements Markham, "can imagine the critical position of a leaky little boat of forty tons like the Niña, rising on the top of a huge Atlantic wave, then plunging into the trough, with the mountainous billows foaming around higher than her mast-head, then rising and plunging down again, the slightest inattention to the helm making destruction certain, while green seas washed over her fore and aft." There must have been at least a few of the twenty-five men aboard able to devote to their own safety an almost superhuman effort. On March 15, 1493, the Niña reached Palos, and Martin Pinzon with the Pinta, on the evening of the same day, also put into the harbor. A few days before, he had arrived at the harbor of Bayonne in Galicia.

As far as we know from the records, and they are quite full, every member of the crews of both vessels was alive and well. One Indian had died on the very day that the Niña arrived, and three others were too ill to travel farther than Palos. No champion of the American origin of syphilis has tried to prove that the death or the sickness was due to syphilis. In the letter of Columbus, written in February, 1493, and dated on board the Niña, there is no mention or suggestion of any strange disease. There was on

the Niña a physician, Maestro Alonzo of Moguer, who would undoubtedly have reported to Columbus the presence of any new malady among the sailors. If these men were infected in Hayti, there was ample time for some symptoms to appear while they were still on the ocean. The voyage home in those open boats in rough weather, under sanitary conditions that must have been appalling, ought to have been marked, in a few cases at least, by symptoms of early syphilis, which in that day was almost malignant, and frightful even in its initial stage.

Fracastor's description is of a disease that would not have escaped attention. "Animum tristitia quaedam detinebat," he says. Depressed spirits, pallor, lassitude, foul ulcers of the genitals, sores on the lips, tonsils, and nose; terrible pains in the joints, bones, muscles, and nerves; emaciation, no desire for food, swelling of the legs and face, loss of hair, fever and prostration (*amor decubitus*)—these were common and even early symptoms in that first epidemic. Perhaps sufficient time had not elapsed to produce any secondary symptoms, but it seems impossible to believe that if there were infected men in either the Pinta or the Niña, they could have escaped the notice of their companions. The gossip of the sailors about a new venereal disease would have excited the curiosity of the people quite as much as the appearance of the Indians. These men had weathered a severe storm; they were exposed to cold and wet, and were in want of food; and yet they brought their vessels safe to port,—a feat that could hardly have been accomplished if *amor decubitus* had been the rule.

From Palos, Columbus went overland to Seville, which he entered triumphantly on Palm Sunday, 1493. He was accompanied by Juan Niño, master and part owner of the Niña, by the pilots and several seamen, and by six Indians. In that crowd of spectators was Las Casas, destined to be one of the great men of the world, and the most trustworthy historian of Columbus. He was then but twenty years of age.

After spending several weeks in this city, Columbus was summoned to attend court in Barcelona, where he arrived, after making the journey by land, about the middle of April. In the parade around the city we are told that he was preceded by the Indians and by sailors of the Niña. It will be remembered that Martin Pinzon deserted him with the Pinta and received a cold welcome when he arrived at Palos. Pinzon, who was then about fifty years of age, died three days after his arrival. His crushing reproof from the Spanish court, forbidding him to appear in the presence of the sovereigns, is supposed to have hastened his end. There is no mention of the sailors of the Pinta, and it may be that on account of the desertion of their master and his subsequent death, they had no desire to accompany Columbus to Barcelona.

All these facts must be grasped in order that

we may get some estimate of the possible sources of infection in Barcelona. It is probable that not more than twenty-five of the sailors were present, and if most of them were infected they must have been in the midst of severe secondary symptoms. Yet of such conditions there is no trustworthy contemporary record, although Bloch cites that of Diaz de Isla, which I shall consider later. On May 28, 1493, Columbus left Barcelona and immediately began to prepare for his second voyage, on which he embarked at Cadiz, September 25, 1493, with seventeen vessels overcrowded with fifteen hundred men.

The physician on this voyage was Dr. Diego Alvarez Chanca of Seville, a man of high reputation for skill and learning. He was ordered to join the expedition, not only to take medical charge, but also to report upon the rare and unknown plants of the Indies. Evidently he was a man of more than ordinary education. In a letter to Spain in the latter part of 1493, he makes no mention of any new diseases. This is also true of the letter of Columbus dated January, 1494. Of sickness there was plenty, but it was due to the hardships of the voyage, the salt provisions, the mouldy biscuits, the water, and the climate. "One-third of the people," says Chanca, "have fallen sick within the last four days, which I think has principally arisen from the toil and the privation of the journey. Another cause has been the variability of the climate." The letter of Columbus mentioned above confirms this statement. Moreover, although the journal of the second voyage of Columbus is lost, much information concerning it was given to Bernaldez by Chanca. Besides, on his return from the second voyage, Columbus stayed at the house of Bernaldez, who thus heard the story of that voyage from the Admiral himself, while it was still fresh in his mind. Columbus also left with him written memoranda which Bernaldez used in his *Historia de los Reyes Catolicos*, which is considered the highest authority on this particular voyage. In it we can find no mention of this new disease, although the author was in possession of many facts that he obtained from Chanca.

On the 2d of February, 1494, Antonio Torres, in command of nine of the vessels, sailed on the return voyage to Spain. In July, 1494, Margerite, one of Columbus's lieutenants, deserted his post, and seizing three vessels sailed away to Spain with a number of other deserters. This man had been in command of a fort in Hayti, where his rule was characterized by idleness, robbery and the outraging of women. These events put back in Spain in 1494 a part of that second expedition. In June, 1496, Columbus himself returned with two vessels overloaded with more than two hundred homesick passengers, a haggard and starving company.

The story of Columbus for the present purpose need be pursued no further, but these historical facts seem to be necessary in order to

show the impossibility of adjusting to them the evidence on which Iwan Bloch rests his case. Here it will be well to ponder over the words of John Fiske, who says, in speaking of historical blunders that arise from things that are spoken: "In order to arrive at historical truth, it is not enough to obtain correct pieces of facts; it is necessary to group the items in their causal relation and to estimate the precise weight that must be accorded to each in the total result. To do this is so often difficult that half truths are very commonly offered in place of whole truths, and it sometimes happens that of all the forms of falsehood none is so misleading as the half truth."

The first main fact in the evidence is a letter of Peter Martyr, dated 1488, and addressed to Pedro Arias Barbossa, professor of Greek at Salamanca. Martyr was born in 1457 and died in 1526. His voluminous correspondence consists of eight hundred and thirty letters, which were assembled in 1530 by Aleida des Henaris and later, in 1670, re-edited at Amsterdam. In the letter referred to, Martyr mentions the *morbus galliens*. "*Ario Lusitano Græcæ Litteras Salutiæque Profitenti; Valentidenario. In peculiarem te nostræ tempestatis morbum, cui appellatione Hispana Bimarium dicitur, ab Italico morbus Gallienus, medicorum Elephantiam alii aliter appellant, incidisse præcipitum. Hæc ad me scribis pede.*" etc. "To Arias of Portugal, Professor of Greek at Salamanca, good health:—You write me freely that you have suddenly fallen into that peculiar disease of our own time which is called by the Spanish name Bimas, by the Italians, Morbus Gallienus, some doctors call it Elephantia, some other names." Bloch cites Von Ranke, Schumacher, and Bernays as proof that several of Martyr's letters are wrongly dated. Bernays points out that this letter in particular must bear the wrong date, because the history of the University of Salamanca shows that there was no chair in the Greek language until 1508. Now as long ago as 1823, Dominico Thiene, an opponent of the American origin of syphilis, mentions this same letter and refuses to accept it as evidence for the same reason. Our own historian, William H. Prescott, also an opponent of the American origin, remarks that Thiene does not cite his authority for limiting the introduction of Greek at Salamanca to 1508. Prescott states that it was probably Pedro Chacón, who in 1499 compiled the history of the University. The accuracy of his chronology, however, as we will be doubted from a cross-reference on the same page with the date referred to, when he speaks of Queen Isabella's crowning the Crown in 1512. Prescott also states that Barbossa was professor of Greek at Salamanca in 1488, and that he was a pupil of Andreas Recolletus. Andreas Recolletus, an draught of a physician, was a student of Luchina, professor of Greek at Madrid, and a professor at the University of Quito.

Barbosa, *Bibliotheca Lusitana*, tom 1, p. 77.) "Arias of Portugal, for forty years and more, taught at Salamanca with great credit not only the Latin language, but also the Greek." Barbosa died in his native Portugal in 1530, where he passed several years before his death, and therefore this letter places him at Salamanca at the time indicated by Martyr.

Furthermore, Rashdall states that Salamanca was one of the five universities at which the Council of Vienna in 1312 directed that "Professors of the Greek, Arabic, Chaldee and Hebrew languages should be maintained." This University was founded about 1230, and by the sixteenth century was one of the largest in Europe. The higher education of women had already begun there. It was from Salamanca that Queen Isabella summoned the brilliant Dona Beatrix Galindo to teach her Latin. Here also Dona Lucia de Medrano publicly lectured on the Latin language. The matriculation book in 1552 gives the names of 6328 students. It is indeed strange to find such a progressive institution lacking a chair in Greek before 1508, and it is an amusing fact to find that the argument in favor of the American origin of syphilis must be constructed on the absence of a Greek professorship at a great university. Even if we concede at the outset this one point to Bloch, we have at least shown that if Greek was not taught at Salamanca before 1508, Martyr's letter must have been written fifteen years or more after the discovery of America, and its author, had he heard of the American origin of syphilis, would undoubtedly have mentioned the fact together with the other terms which he used in commenting on the disease.

The evidence most emphasized by Bloch comes from a Portuguese physician, Ruy Diaz de Isla, who was born in 1462 and died in 1542. This physician is the author of two works published in 1539 and 1542, respectively. He is supposed to have been in Barcelona in 1493, where he witnessed the reception to Columbus on his return from the New World. Later he practised in Seville, and afterwards spent ten years as surgeon at the Hospital of All Saints, in Lisbon. Modesty was not one of his virtues. He wishes to impress us with his long experience. He says that he is convinced that syphilis came from the island discovered by Columbus, and that it is contagious in its own peculiar way. It was easily acquired and soon manifested itself in the fleet in the case of a pilot from Palos named Pinzon, and in others in whom the aforesaid disease was advancing. This statement, upon which Bloch lays so much stress, is taken from an edition of de Isla's, known as the *Codex*, which was first published between 1510 and 1520, and is supposed to have been discovered in the national library of Madrid by Montejo, a Spanish physician. Bloch tells us that he was born in 1825 and died in 1890. Montejo's first work on the history of syphilis appeared in 1857. The *Codex* is dedi-

cated to King Manuel of Portugal, who died in 1521. Prokseh remarks that the date 1510 is certainly erroneous because in this book an event of 1514 is mentioned. It was written then, not earlier than 1515, and this places it more than twenty years after the discovery of America. I cannot appreciate Bloch's enthusiastic remark that this important work is twenty years older than the edition of 1539.

In the *Codex* occurs the following passage: "Segun que por muy larga y cierta experiencia se ha hallado, y como esta ysla fue descubierta y hallada por El Almirante Don Cristoval Colon al presente teniendo platia y comunicacion en las yndias Como el de su propia calidad sea contagioso, facilmente se les apego. E luego fue visto en la propia armada *em hun piloto de Palos que se llamava Pincon* y en otros que el dicho mal fue prosiguiendo." (This is the passage that I have rather freely translated in the indirect quotation in the preceding paragraph.) Compare this with the passage taken from the edition known as "tractado Contra el Mal Serpentino," published in Seville in 1539: "Segun que por muy larga y cierta experiencia se ha hallado. E como esta ysla fue descubierta y hallada por el almirante don Xristpoual Colon, al presente teniendo platia y comunicacion con la gente d'lla. E como el de su propia calidad sea contagioso facilmente seles apego: y luego fue vista en la propia armada." It requires no knowledge of Spanish to see by mere inspection that these passages are almost identical except in the last line, in which Pinzon is definitely accused of being syphilitic.

One cannot help asking if the *Codex* is an edition that has been tampered with by inserting this accusation against a prominent member of the first crew of Columbus. If the *Codex* was really written by Diaz de Isla, did its author put it aside through fear of publishing it during the lifetime of Vincente Pinzon? Moreover, if it was published as early as 1515, when Pinzon was still living, why is it that we have no record either of Pinzon's own protest against it, or the protest of his family? Is it possible that the supporters of the American origin of syphilis, in order to strengthen their case, have deliberately made this charge? Almost a quarter of a century had elapsed since the date of the return of the Admiral from that first voyage, and yet no other writer had made any mention of the presence of the disease in that first crew.

Bloch praises de Isla as a skillful physician, with a deep knowledge of syphilis and its treatment, but he lacks a sense of humor when he tries to excuse the assertion of de Isla that syphilis in its pustular form attacks vegetables, especially the cabbage. In 1823 Thiene refused to accept the evidence of de Isla on the ground that Girtaner did not give his authority for the facts concerning the life of this physician. Furthermore, Thiene objected to the lack of the testimony of eye witnesses to support the statement of Bloch's authority concerning the pres-

long ago disproved. His first visit was in 1502, a date important to note, because by the time Las Casas arrived, syphilis was widely spread among the inhabitants of the new world. The passage which Bloch cites from this author is in the fifth volume of the *Historia*, which was written when Las Casas was at least eighty-five years of age, about sixty-five years after the discovery of America. A translation of that passage follows:—

"There were and still are in this island two things which in the beginning were very dangerous to the Spaniards. One is the sickness of Las Bubas, which in Italy is called the French disease. It is the truth, however, that it came from this island with the first Indians when the Admiral Christopher Columbus returned with the news of the discovery of the Indies. The Indians I saw afterwards in Seville, and they may have brought the disease into Spain either by infecting the air or in some other way; or it was brought by some Spaniards already infected, in the first return voyage to Seville. This could be from 1494 to 1496. Moreover, at this time King Charles of France passed into Italy with a great army, which became afflicted with this contagion. For this reason the Italians think that it was spread, by these soldiers, and from this time on they called it the French disease. I asked several times the Indians of this island if this disease was very old, and they replied that it was present there before the first Christians came. In fact, its origin was beyond their memory, and this no one ought to doubt.

"It appears, however, that Divine Providence has provided for it a special medicine which is, as I have stated above, the wood of the guaiac tree. It is especially noticeable that all the Spaniards who did not practise chastity were infected, and not one in a hundred escaped if the woman had the disease. The Indians, men and women, who have it are very little troubled by it, no more than if they had smallpox, but the Spaniards are painfully afflicted and are in great and continual torment, especially before the pox break out."

In the earlier chapters of the *Historia*, in which Las Casas shows such an intimate knowledge of the voyages of Columbus, he does not mention the disease in connection with the Indians or the members of the crew. Remember that he wrote the passage quoted above years afterwards, when he was undoubtedly influenced by the theory that the infection was brought from the Indies. His inquiries of the natives concerning syphilis cannot be given serious consideration, because neither he nor the natives knew enough about the disease to hold an intelligible conversation. Bloch himself characterizes as utterly worthless certain descriptions of and references to diseases of the genital organs by ancient and medieval authors that could easily be taken as indicating syphilis. Yet he does not consider that the Indians with

whom Las Casas talked may have had some other disease in mind, and that consequently their opinions are as utterly worthless as the descriptions of our ancient, but highly civilized and educated, authors. Las Casas arrived in the New World at a time when the disease had already been brought from Europe, and he must have been impressed by its malignancy in that first epidemic. Like Oviedo, he also observes that although Providence has inflicted this disease upon the natives of Hayti, divine justice has made some compensation by providing on the island a cure in the guaiac tree. I wonder what Las Casas would have thought had he known that the mercy of Providence was truly expressed in those ancient quicksilver mines in Almadén, in his native Spain, from which, for centuries before and after his time, the world derived its largest supply of the real cure for syphilis. Would he have thought that the pox was of Spanish origin, or would he have clung to his first belief and decided that this wonderful deposit of mercury in Almadén was intended for the ills of the poor heathen, to whom Columbus, under the patronage of Spain, was sent as an instrument of Divine Providence?

When he wrote this chapter, Las Casas evidently did not know the value of mercurial treatment. Moreover, Fracastorius, one of the few men of mighty intellect that have graced our profession, had refused already, at this time, to accept the theory of the American origin, and had written his poem, *Syphilis sive Morbus Gallicus*, which contains a vivid description of the treatment by mercurial inunctions. Had Las Casas been familiar with the discussions of the time concerning this disease, he would undoubtedly have given some thought to the opinion of the learned author of this poem. In that nineteenth chapter of the fifth volume of the *Historia*, he was simply expressing some random thoughts that should not be interpreted too literally. His work in the world was far more important than Bloch seems to realize. To reduce him to the rôle of an amateur syphilographer is as ridiculous as to cast the star in the rôle of one of the strolling players in Hamlet. The American physician who would know him intimately can find no more profitable task than the reading of the story of Las Casas and his brother Dominicans of that little monastery in Guatemala. "We cannot make him anything else," says John Fiske, "but an antagonist of human slavery in all its forms, and the mightiest and most effective antagonist that has ever lived. Subtract his glorious life from the history of the past, and we might still be waiting, sick with hope deferred, for a Wilberforce, a Garrison, or a Lincoln."

Although Bloch is always ready to quote Las Casas in support of his pet theory, he ignores that author's story of the first voyage of Columbus, which is recognized as authentic by every genuine historian. For instance, he gives the

can be found no more splendid lesson of perseverance, and courage, and amazing achievement, to teach to each succeeding generation, than the untarnished story of Christopher Columbus and his crew. Let him be ashamed to link this historic event with the curse of the spirochete, and let him often pay to the discoverer of his country the tribute so aptly quoted by Professor Edward Channing,

"What if wise men as far back as Ptolemy

Judged that the earth, like an orange, was round,  
None of them ever said, 'Come along, follow me!'

Sail to the West, and the East will be found."

## Massachusetts Anti-Tuberculosis League.

### SECOND ANNUAL MEETING AND CONFERENCE, APRIL 27, 1916.

#### OPENING REMARKS OF THE PRESIDENT.

By VINCENT Y. BOWDITCH, M.D., BOSTON.

AT this, our second annual meeting, it is well for us to ponder upon the purpose of our League, to take account of what has been accomplished during the past year, and to see wherein we can accomplish the greatest good in the months to come. We cannot emphasize too strongly the purpose for which the League was established, viz.: to keep watch upon the work which is being done throughout the State, to note and encourage those communities where work is being actively done, to stimulate to action those in which possibly there has been, and may still be, indifference as to the importance of all anti-tuberculosis work.

Most, if not all, of you are familiar with the leaflet sent out by our secretary last autumn, signed by our Commissioner of Health, Dr. McLaughlin, by Dr. A. K. Stone, and myself as Chairman of the Trustees of the Massachusetts Hospitals for Consumptives and President of this League respectively. This leaflet was published to counteract a possible tendency towards

the belief that, in consequence of the increase in the number of anti-tuberculosis societies, there is no further need of agitation of this question, which means so much to the health of our State and country.

Strong influence has already been brought to bear upon our legislature by our League in matters of vital importance to the anti-tuberculosis question. Coming as the united opinion of an association, such influence carries greater weight than that emanating from individual effort, no matter how earnest the latter may be.

The results accomplished by our Health Commissioners during the past year in enforcing laws made for the establishment of dispensaries and hospitals in certain communities of Massachusetts have been most gratifying. I feel sure, however, the Commissioners would be among the first to acknowledge the help obtained by the expressions of opinion from, not only our League, but from the Trustees of the Massachusetts Hospitals for Consumptives and others before the legislative leaders.

Much remains to be done, however, and far from feeling that the necessity for such organization as this is lessening, I know that those who are most conversant with facts believe that there never was greater need than now for persistent endeavor on our part to push through legislation in the future. In this connection, I heartily recommend for the perusal of all of our members the admirable paper by Dr. Eugene R. Kelley of the Department of Health, upon Tuberculosis Dispensaries, printed in the Public Health Bulletin of October, 1915, Vol. 2, No. 9. While he naturally recognizes that the work is far from perfect, and leaves much to be desired, yet the fact that the fifty-four cities and towns of Massachusetts which now maintain a dispensary service represent approximately 80 per cent. of the population of the Commonwealth, is very encouraging, considering the comparatively short time since this movement was begun.

It is the function of this League, moreover, to keep watch upon the work thus far accomplished and to see that it does not lag from lack of interest.

Striking examples of what has been admirably done in certain cities and towns are now before us. I cannot refrain from singling out one or two which have come under my special notice, as being an inspiration to others who may be beginning.

No one who has studied the facts about anti-tuberculosis work in New Bedford and who has visited the admirably arranged Sassaquin Hospital in the suburbs of that city, can fail to be struck by the possibilities of what can be done to alleviate the sufferings of the poorer classes and to lessen the ravages of tuberculosis. This hospital, with its remarkable atmosphere of cheer, among even the sickest patients, its practical and at the same time economical construction, may well serve as an example for others to

follow. The fact that it has already been able to cope successfully with the difficult question of the hospitalization of far-advanced cases in New Bedford, that it combines also the elements of a sanatorium and an open-air school for tuberculous children, and finally that it is eagerly sought out by patients and their friends, is one of the most helpful and inspiring examples of what can be done that I know. The fact that that has been largely the work of one of our most zealous and efficient anti-tuberculosis workers, the Rev. William Geoghegan, deserves special mention.

Incidentally, it is an interesting fact that the origin of this movement in New Bedford came from among the foreign class,—the Portuguese, who began with a very small and quite inadequate collection of mere huts for the reception of far-advanced cases. It speaks equally well for the spirit among these people that they cheerfully placed the work which they had begun into the hands of Mr. Geoghegan and his associates, without demanding special recognition or special privileges for themselves. The remarkable growth of the institution in five years, its removal to an excellent situation in the suburbs, is due to the enthusiasm and ability of well-known citizens, notably the late Dr. William N. Swift, and especially to the unrelenting zeal of Mr. Geoghegan.

Beverly is another instance of a city which has made a striking advance in grappling with this question during the past year, largely due to the energy and enthusiasm of those who began the work there—members of our League.

In thus singling out these striking instances, one recognizes also that in many directions throughout the State progressive work is being admirably done, which augurs well for the future.

One need not necessarily be a member of any local anti-tuberculosis society, but as a member of our League he can effectively use his influence in various matters which bear upon the health of the community in which he lives. To help keep alive the knowledge that no patient should be put off by a hasty or careless diagnosis when he is showing persistent signs suggestive of tubercular trouble; to teach others the value of fresh air, good food, regular living, as a means of prevention of disease,—these are subjects in which every member of the League can use his personal influence with marked benefit to the health of all with whom he comes in contact.

In my opening remarks at our meeting last year I mentioned one feature of the anti-tuberculosis campaign which needs the thoughtful consideration of every one, viz.: the control of the incurable consumptive, who by wilful disregard of others, and in spite of protests, persists in filthy habits, thereby spreading infection.

Naturally there comes to most of us a repugnance to drastic methods in controlling such people, but it can and should be accomplished

with firmness consistent with kindness and due regard to the rights of every one. Something must be done in this direction ere long if we are to be successful in controlling the ravages of tuberculosis.

The experience in Australia of Dr. Victor G. Heiser, ex-Director of Health, Philippine Islands, is very significant. By stringent measures there, he tells us that tuberculosis is fast becoming a controllable disease, and isolation of incurable cases is resorted to without delay. Incidentally, other methods which might well be adopted in our community have obtained in Australia, the details of which Dr. Heiser has given in his comparatively recent address in this country.\* It should be read by everyone. In the State of Victoria, Australia, every physician who reports a case of tuberculosis is paid a fee of ten shillings (\$2.50). The Health Department then sends a physician whose duty it is to follow the case. If the family is able to adopt proper precautions at home, the patient is left there and kept under supervision; otherwise, he is removed to a proper hospital or sanatorium. Thus far this method has been adopted, we are told, with perfect success. Why should we not do likewise? Even granting that social conditions possibly make these methods more easily adopted there than here, it should not discourage us in our efforts to bring about the same desirable results. As stated last year, up to 1912 four States had made laws relative to the care of incurable consumptives. New Jersey, New York, Wisconsin and Minnesota, but the marked dissimilarity in legislation makes it difficult to judge of the comparative advantages of each. Results in those States, however, do not compare at all favorably with those of Australia, as stated by Dr. Heiser.

An attempt was made last January to pass a bill through our legislature which should enable us to use strong measures with incurable consumptives, but, as was expected, the bill was not engrossed, for our people have not yet been educated to the point of insisting that such laws offered by our Health Commission shall not only be made, but enforced.

Here again comes the opportunity for the members of our League to influence those with whom they come in contact.

During the last year there has been a marked increase in the number of anti-tuberculosis organizations which have been organized. It is to be hoped that the greater number of these organizations will be of the type which will do more than to hold meetings and to publish reports, but which will be of the type which will do more to educate the public and to influence the legislature.

At the same time, it is to be hoped that the organizations which are already in existence will be able to do more to educate the public and to influence the legislature. It is to be hoped that the organizations which are already in existence will be able to do more to educate the public and to influence the legislature.

It is to be hoped that the organizations which are already in existence will be able to do more to educate the public and to influence the legislature. It is to be hoped that the organizations which are already in existence will be able to do more to educate the public and to influence the legislature.

points already touched upon last year as among the most important in the anti-tuberculosis campaign.

First, we must have a more rigid enforcement of the present law requiring all cases of tuberculosis to be reported by the attending physician to the proper authorities. That such enforcement in the present state of public opinion may be at times wrongly a source of embarrassment to the physician in attendance must be recognized; at the same time, the public must be taught that registration, not necessarily meaning discomfort to the patient or friends, is absolutely necessary if the disease is to be brought under control in the future.

Second, a constant endeavor should be made to induce proprietors of mills, factories, and shops to watch the health of their employees more carefully and attend to the hygienic surroundings of their workers. While much has been done in this direction, there is vast room for improvement in the future.

Third, the establishment of open-air schools, not only for those already ill, but for those not afflicted but who need to be fortified against disease, should be urged. No one who has visited the open-air schools in the sanatoria at Westfield, and at Sassaquin in New Bedford, can fail to be impressed by what can be done by such measures to restore health to tuberculous children. I look forward to the day when similar methods can be adopted in all schools, with infinite benefit to the cause of Preventive Medicine.

#### THE PLAN OF THE STATE DEPARTMENT OF HEALTH FOR MORE TUBERCULOSIS HOSPITALS.

By EUGENE R. KELLEY, M.D., Boston,

*Director Division of Communicable Diseases, State Department of Health.*

The plan of the State Department of Health for more tuberculosis hospitals as incorporated in House Bill No. 2042, now before the General Court for consideration, is briefly as follows:

It frankly recognizes two important facts. The first is that there is now inadequate hospital provision for many communities in the Commonwealth, and, generally speaking, no local hospital provision for consumptives for towns of under 10,000 anywhere. The other fact that is equally apparent is that it is impractical and uneconomical to expect small cities and towns to erect and maintain individual hospitals for the care of their consumptives.

A possible way out of this dilemma is the one that was contemplated by the law now in effect, that is, authorizing cities and towns jointly to erect hospitals or to make arrangements for the care of consumptives from small places in hospitals in the adjoining larger cities and towns. From a practical standpoint, this plan has not

been effective, and it is very evident that it never will be. The reason for this is very simple. The tendency is for each community to build scarcely enough beds for its own cases; therefore an agreement to care for patients from smaller, neighboring towns, of which there are several now in existence in the State, is always conditional upon there being available beds which are not desired for the inhabitants of the city that is maintaining the hospital. Such being the situation, it is evident that the only solution that will provide adequate hospital beds for consumptives is one which will procure beds that will be available to citizens of all the towns, no matter how small, when needed.

As a matter of practical experience in this State and other parts of the world, another consideration, only less important than having the beds at all, is the desirability of having these consumptive hospital beds available within reasonable access to the patients' homes.

After a long detailed examination of the situation and a discussion of all the possibilities, the State District Health Officers and the other officials of the State Department of Health unanimously agreed, from the showing made by the investigations of the District Health Officers, that it would not be feasible to put up any plan for coöperative hospitals, to serve a number of cities and towns unless it recognized the existing machinery of government. The only existing machinery of government that stands between the State and the individual cities and towns is the county government. Therefore, it was felt that the most satisfactory plan from a practical standpoint would be one which would utilize the already existing governmental agencies as represented by the county officials.

From the viewpoint of building hospitals only, it would, of course, be equally possible to have additional hospitals built by the State itself. There are several serious obstacles to this plan. In the first place, the State already has invested a very large sum of money in its five institutions for the care of the tuberculous. These institutions do not work out satisfactorily as advanced hospitals, although under present conditions the beds in these institutions are so largely monopolized by the type of case which really belongs in an advanced hospital that it is impossible for them to fulfill their proper functions as sanatoria for the arresting and curing of earlier, favorable cases.

A second and greater objection to the scheme of the State building additional institutions lies in the fact that many of the already existing city and private institutions could be readily enlarged to serve a very much larger district than the immediate city or town for whose use they are now exclusively maintained, but if the State began building additional hospitals it would mean that there would never be any extension of these institutions for the communities which are in close proximity to these local hospitals. From many standpoints, it is more desirable to utilize

# THE RELATION OF THE ANTI-TUBERCULOSIS SOCIETY TO THE LOCAL BOARD OF HEALTH.

BY JOHN W. TAPPER, LYNN, MASS.,

*Chairman, Board of Health.*

As a factor in the conservation of human life, the Anti-Tuberculosis Society can, and should, be one of the most valuable units of the public health machinery. Its field of action is not only extensive but offers immense possibilities as well. Its value and usefulness, however, depend wholly upon wise counsel and the adoption by the society of a definite, fixed policy, so that, as a result of its efforts, may be realized the maximum of benefit. Today, apparently, the one great weakness in the battle against tuberculosis is lack of coöperation among the available forces, because of which we are wasting a lot of valuable energy. I believe this weakness can be wholly eliminated, if frequent conferences are held between the several societies and the local boards of health, upon whom rests, as the name indicates, the burden of conserving the public health. These boards are required to direct their forces not only against tuberculosis, but against many other diseases that may threaten human life. For this very reason, boards of health are given greater power than is given to any other unit of the civic government. The Legislature, however, has very wisely surrounded these boards with certain laws designed to govern their actions, and no matter what the particular type of case may be, the health board must base its actions upon the law in the case, and what is revealed by its investigations. In fact, in all of its efforts and its actions, it is surrounded by law; of which, the law of settlements plays an important part, and the final disposition of the case must depend upon what its investigations reveal. In this phase of its work, it may be materially aided through the assistance of any society whose object is the elimination of some one particular health danger. In this respect, it is true, that today it is possible for almost every health department to avail itself of the assistance of one of a number of different organizations who are seeking to aid the health and comfort of their community, through the reduction of some particular type of disease, in which they have become interested. Of these several organizations that might be mentioned, and which are doing good work, are those interested in Child Welfare, Community Betterment, The Housing Problem, Baby Clinics, Modified Milk Stations, and numerous others; all very worthy and deserving of encouragement. But none of these can be of real value, unless they work in complete harmony with the local board of health. Unfortunately, some do not work with us as they should. This may not be wholly their fault, but, regardless of whose fault it may be, it should not exist. It can be avoided if we but foster the get-together spirit. I wish you to appreciate the real spirit of this criticism, for I

am only trying to point out the many difficulties that boards of health must overcome because the several different organizations at times act independently; that is, oftentimes a board of health is hampered in its work by the actions of an organization which, in its eagerness to do good, defeats the very object of its efforts, simply because it fails to appreciate the value of coöperative work. In other words, it fails because it attempts to solve a problem, the burden of whose solution the State has placed squarely upon the shoulders of the local board of health, and at this very point, we may well ask this question: The State having so placed the burden, can the local board of health, alone, solve the Public Health Problem? I am firmly convinced that no board, no matter how well equipped, can solve this problem without the assistance, backing, and coöperation of the public, and next to the public's support, one of a department's greatest assets is the support of a well organized anti-society, and of these, the greatest opportunity for world-wide good is offered the Anti-Tuberculosis Society. It has been well said, that a community may have as much health as it is willing to pay for. Good health is purchasable, but those agencies entrusted with making the purchase should be chosen wisely and given the coöperation of every individual and organization, that we may in return receive every possible benefit that coöperative efficiency can produce. And here, we may well consider just what part an Anti-Tuberculosis Society may play, and what may be its ideal relation to a local board of health. Quoting from a pamphlet issued in January last by your organization, you say, "Because the State is requiring the construction of tuberculosis hospitals and the maintenance of tuberculosis dispensaries, the impression has gone abroad that there is no further need of an Anti-Tuberculosis Society and committees interested." In the suppression of tuberculosis, if such an impression is really abroad, I am, personally, not in accord with it. Based upon an actual experience covering a period of several years in health work, I am convinced that the need of an Anti-Tuberculosis Society exists today to a greater extent than ever. To discontinue the effective work of the Massachusetts Anti-Tuberculosis League, with its kindred organizations, would, indeed, be not only a step backward, but a most serious blow to the cause. I believe, if it were possible for me to get an expression from the thousands of unfortunate victims throughout this State, their unanimous verdict would be: Tell the League that we need them now as we never needed them before; tell them that we have faith in them, and believe that they should continue to be as a beacon light toward which we may steer our frail craft of hope, confident that, under their watchful care and guidance, our emancipation from this awful affliction will be the more quickly realized. This, I firmly believe, would be the message they would tell me to deliver to you today and, in

giving you this message, I feel that the responsibility rests upon me to urge you to study well the means by which you can best serve them. Let me urge the great value of efficient coöperation with the local boards of health. That is your sphere, and that the only road to your ultimate success. From your past experiences you must have a store of knowledge that should prove immensely valuable to you as a guide.

I believe that your work is just beginning and the first problem that you have to solve in this great crusade is the complete development of a modern anti-tuberculosis organization; that you may not only hold the ground already won, but that you may be enabled to push on to a complete victory. Such an organization should include a working unit in every community, thoroughly organized in every detail. I am quite confident of the good results that would accrue, if these city and town societies were made a working unit of a State league, made up of representatives from the local anti-societies. Frequent conferences should be held with the local board of health in order that duplication of effort, and consequent embarrassing situations, may be avoided. It is not my intention in any way to attempt to map out in detail any definite line of action, because I am too well aware of the widely different conditions that obtain in the different communities. I fully realize that in the community maintaining an active health department the real function of an Anti-Tuberculosis Society is more of an educational one. It should, in a great measure, confine its efforts to the dissemination of information, covering not only the care of predisposed tubercular persons, but including in its activities a complete study of the entire social problem as well. This study may well include the housing and lodging house problems; the employment of arrested cases and every other phase of their social welfare. This work you may well do, but it should be carried on in complete harmony and coöperation with the local boards of health. You should never attempt to handle an actual case of tuberculosis without first obtaining a complete understanding with the health department, that you may keep fully informed of just what that department may have done in the particular case in which you have become interested. I want to emphasize this point, but to illustrate more fully, let me cite several cases, that I may show you what may rightly be termed ill-advised attempts to handle an actual tuberculosis patient, and its resultant bad effect.

CASE A. This patient was sent by a private society to a local hospital. Diagnosis of tubercular ulcer made. Patient was operated upon. After several weeks' stay in the local hospital, arrangements were made and patient sent to a convalescent charitable home. Upon admission and examination of the patient, the society interested was notified to remove the patient at once as she was suffering from three or four discharging tubercular ulcers on leg, and otherwise not a fit case for this home. The board of health was then notified and

asked to relieve the society. This was done and the patient sent to the local tuberculosis sanatorium, where she should have gone in the first place, and the consequent exposure of others would have been avoided.

CASE B. In this case, the board of health was notified and plans made for the removal and cure of patient, because home conditions were unsatisfactory, and sufficient means to handle case at home were lacking. Consent of patient and mother of patient obtained for removal to sanatorium. After all arrangements for the care and removal of patient had been completed, patient was visited by worker from private society and advised to move from home where they were to another location, and to remain at home. Patient, thinking financial help would come from private society, accepted advice, and disregarded all previous arrangements made by the board of health. After patient had gone to the expense of moving, very little assistance was given by the society who had interfered. This patient lived eleven months. Was a bed case the entire time. After waiting for expected help from this society, and not receiving it, patient and mother realized their mistake, and asked our social worker to provide milk and other necessities. These were provided as patient's condition at this point made removal seem unwise.

CASE C. Board of health was notified, visited patient, found home conditions very bad. Patient was advised to go to our local tuberculosis hospital to await admission to Rutland Sanatorium. Private society advised sending patient to New Hampshire, they paying board for a given number of weeks. Our social worker, knowing the patient's condition, advised against this plan; fearing patient would exercise too much when rest and medical supervision were needed. Notwithstanding this advice, patient went to New Hampshire, remaining there about three months, returning home feeling improved. Visited our dispensary and requested that application be made for admission to the Rutland Sanatorium. This admission was refused because being too far advanced. After many weeks of unsatisfactory home treatment patient entered a local tuberculosis hospital, death occurring a few months later.

CASE D. This patient, a man having a wife and four children, was examined at our local convalescent home, and advised to go to a local tuberculosis hospital pending admission to Rutland Sanatorium. Patient wished to take home treatment, promising to go to dispensary, and if he did not improve to enter the sanatorium. Home conditions were unsatisfactory, but a piazza was put in condition for convalescing purposes. Not improving, patient entered a local hospital; his family were kept from the hospital, as care provided by a mother and father, and other T. B. friends. After three months in hospital, and after taking a long vacation, patient returned as soon as he was able to his home, where he remained previous to his death. He was visited by outside workers, but no family application was made for help. This was a case where the patient and his family were not properly advised, and their financial condition was not taken into consideration time to prevent the patient from returning home. The patient lived about six months.

ing to support his family without the aid of the Poor Department.

You will note in every instance, no attempt was made to work with our local board until the case became a burden and they wanted to drop it.

We might cite a number of other cases to show how an active health department may be handicapped by workers seeking to do good, but who oftentimes are only undoing work which may have taken the health department several weeks to accomplish. Our department early recognized the fact, that every case presents some peculiar phase which requires individual treatment of its own. In fact, all cases differ, thus making it impossible to adopt any hard and fast rule to cover all cases alike. It also frequently happens that a physician, for reasons best known to himself, and in the interest of his patient, deems it wise not to make known to his patient just what his or her actual condition might be. Our board, appreciating this situation, has suggested to all local physicians, that in the event of their having a patient from whom they wish temporarily to withhold the true diagnosis of their case, our department, if requested, would defer its action until such time as the physician might feel that we could with safety take up the case. In almost every instance we find that this rule works decidedly in the interest of the patient and for the better understanding between the physicians and the board of health. The public is safeguarded and the comfort and happiness of the patient are not disturbed. It also encourages that get-together spirit, so essential if success in this fight is to be attained.

In conclusion, may I express it as my firm belief that, having lived to see the dawn of a new knowledge, to have seen that knowledge dispel ignorance and apathy, through which tuberculosis levied its pitiless toll on human life, unheeded and unhampered; having lived to see a substantial decrease in the death rate from this dread disease, we may yet live to see the open gateway to complete success, with all that it means to science, philanthropy, and the brotherhood of man. But you and I can never hope to enter that gateway alone; we must go together.

#### THE VISTING TUBERCULOSIS NURSE.

BY MARY VAN ZILE, R.N., BEVERLY.

In last year's report of the Massachusetts Anti-Tuberculosis League there appeared a paper by Miss Amy F. Aetion on "Tuberculosis Work in this State." With the point of view of the Chief Inspector of Incorporated Charities of the State Board of Charities, Miss Aetion comes to the conclusion that the chief function of an anti-tuberculosis society is to educate. She says,

"As I conceive it, the work of the private society is to gather information touching cause and prevention of tuberculosis, by studies and other means; to disseminate it as widely as possible; and to interest the public to support necessary legislation." This is to be done by "popular lectures, moving picture films, exhibits in schools, shop windows, etc., leaflets in different languages, popular articles in the press, competitive essays by school children, and all other educational methods which human ingenuity can devise. Ideas presented thus reach a vast number of persons at a stage where suggestions for avoiding this disease may be helpful and before control becomes necessary."

If this is to be done by Anti-Tuberculosis societies, the Public Health Nurse, being the home teacher, must, as the agent of the Society, work on that line. For "it is not what scientists know but what people apply that marks our progress." It may interest you, therefore, to see how a practical nurse had come to this same conclusion, through quite different ramifications of experience.

In the beginning of tuberculosis nursing one is somewhat appalled by the complexity of the problem; sickness of such duration as usually to bring poverty and discouragement, and gradual lowering of the standard of living. One may know tuberculosis from A to Z theoretically and technically, and even the best practice in handling these cases socially, yet the first visit in an afflicted home may seem staggering in its need. To find the wage-earning father needing sanatorium care; the older children with defective eyes and throats and faulty posture, all tending toward infection; to see the baby sickly and miserable despite, perhaps, the best efforts of an ignorant mother. All this makes the nurse feel the necessity to coördinate the organized agencies to help this family. Where shall she begin and where will the process end?

#### Care of the Tuberculous.

First, the public must be educated to provide sufficient and efficient care for its consumptives, enough hospitals so that when the man has consented, after much persuasion, to take sanatorium treatment he will neither die nor become discouraged before being admitted. Also the nurse feels the need of provision for the uncontrollable, careless consumptive, and of the law to enforce his removal if he will not take necessary precautions against infecting his children. Here especially she must have the support of Anti-Tuberculosis Societies in introducing and enforcing good laws. The members of these societies are usually the influential people of the community who, by understanding the need and instructing their legislators, can do much to furnish a background for more efficient work. Dr. Linsley R. Williams of the State Department of Health of New York, speaking of the segregation law in that State said, "Though few cases

have forcibly been sent to hospitals we count ourselves extremely fortunate in having such a law behind our work."

### *Inspection and Regulation of Working Places.*

In her search for the cause of infection with tuberculosis the nurse hears frequently of "the man working beside me who coughed and expectorated constantly"—pointing to the need of more unprejudiced inspection of working places. These older children when sent to work should not carry infection into the home. The Anti-Tuberculosis Society may take its part in regulating the construction of factories and the conditions of work, the wages and hours of employment and in instituting health insurance.

### *Provision of Prescribed Treatment for Children.*

Medical inspection of schools is required by law in Massachusetts, but the child in a family will not be benefited merely by a report from school that his eyesight and teeth are defective, that his adenoids should be removed. *The treatment must be given.* If it is found that the parents have more expenses than can be covered by their wages the city should provide means of making the child an efficient citizen. According to insurance calculations a child between 10 and 20 years is worth \$2,000 to the State, and a wage-earner between 20 and 30 is worth \$4,000. Therefore the city can well afford to spend \$10 a year on the health of each child to save his life and promote his wage-earning efficiency. To be well and healthy the child must have physical development and recreation, and to be happy and healthy-minded he must have culture.

Let the Anti-Tuberculosis Societies encourage the support of gymnasiums and playgrounds, children's libraries and picture galleries. Let them censor, to some extent, the motion picture shows, to see that they are educative and inspiring rather than sensational. Let nature-study be provided to go hand in hand with the school teaching of physiology and hygiene, thus guarding against the mistakes of adolescence.

### *Instruction of the Home Makers.*

We note in our family a sickly baby and others, under-nourished, due probably to low wages and the decrease of income with sickness, but partly due also to the waste of material because of the ignorance of the home maker.

*Instruction of Mothers* should begin with girls of school age and be supplemented later by instruction in care of babies and children. The nurse and visiting housekeeper are the most practical teachers in this line. To demonstrate this need some societies provide visiting housekeepers to begin in the homes of tuberculous patients with instruction in the buying and preparation of food. Later city authorities may become convinced of the economy of such teaching and extend the service.

### *Regulation of Building and Renovation of Houses.*

A very great need in tuberculosis work and in health work, as the nurse sees it, is the building of better houses and the right to condemn and destroy unsuitable tenements. Many a workman spends a quarter of his income on shelter for his family and gets therefrom disease and immorality and unhappiness. *Pure air, pure food and safe water*, with facilities for disposal of waste, are only a fair allowance for all taxpayers. Here the more intelligent citizens can make valuable reforms.

### *Co-operation of all Public and Private Agencies.*

The family problem requires much planning and an appeal to many agencies, public and private. The duty of the nurse and her society is—not to give this aid, but to procure it from the organizations already formed for the relief of just such conditions. The Board of Health is empowered to help in sickness, the Poor Department in poverty, and private relief agencies and clubs have for generations given a helping hand when appealed to. Why, because we are dealing with tuberculosis, need the Anti-Tuberculosis Society be added to the list of relief-giving agencies? In dispensary work the giving of medicines or relief diverts the attention of the patient from the importance of the physician's advice and frequently leads to needless pauperization.

Much more profitable and constructive is the education which may prevent sickness and so strike at the root of the difficulty.

### *Co-ordination of the Public Health Nursing of the Community.*

The great waste in the nursing field is in duplication of effort. When the school nurse and the district nurse and the tuberculosis nurse are found to be visiting this family for different purposes and at different times, they will give conflicting advice, and must keep unnecessary records. The result is confusion of mind for the family, and the loss of the personal influence of any one nurse.

So valuable an asset in public health nursing is the fellow-feeling between nurse and patient, that any amount of technique and system may well be sacrificed for this human touch. When the time comes to persuade this man to go to the sanatorium, it will be the nurse who has helped in other emergencies—when the baby was born, when the children were sent to school or to work, who will be able to reach the father to save his health for his family.

It is most desirable to work toward the organization of all public health nursing under one supervisor, as is being done in New York, Cleveland, Boston, Fall River, Detroit, Chicago, St. Louis. Especially in areas for new work in smaller communities it is well to co-ordinate the nursing, better still to place the public health

the care of all indigent sick. Here can be centralized all public care, including that of the city physician, the dispensary and the school physician, making use also of the power of boards of health and the facilities of private agencies.

But above all the system and the executive efficiency, the visiting nurse must herself have the touch feeling with her patient. She must see his predicament as he sees it and adjust her plan to his individual need, remembering always that though she may procure for him and his family all the advice of the medical authorities and all the goods of her co-operating agencies, without charity it will profit him nothing. He will become embittered and disheartened unless by her courage and helpful spirit she can show him the way out, the purpose and object of all his struggle for health.

### TUBERCULOSIS IN RURAL COMMUNITIES.

BY VANDEPOEL ADRIANCE, M.D., WILLIAMSTOWN, MASS.

THE mortality rate of New York City is now lower than that of the rural part of New York state. A few years ago this would have seemed quite impossible, for the opposite relationship prevailed. The science of sanitation has apparently accomplished a reversal of what ordinarily prevails. This can be explained only by assuming that the inhabitants of the countryside are not receiving the same good care that protects the inhabitants of our greatest city from preventative disease.

In matters pertaining to the disease we are discussing today, namely, tuberculosis, the rural population of New York as well as Massachusetts may well consider that they do not have as much done for them as the members of the cities of their respective states. The problems of tuberculosis have been faced in the cities of our Commonwealth and when the cities have been tardy in providing sanatoria and dispensaries the State Board of Health has called attention to delinquencies. The state has overseen, encouraged and even forced some control of the tuberculosis problems in cities over 10,000. This touches two and one-half million lives, but more than three quarters of a million living in towns of less population, and particularly in the farming districts of our countryside, may well consider that they have been neglected. Unfortunately although tuberculosis reaps a large harvest in their midst these people are apt to think the factor too small to be seriously considered. They will be found not only indifferent but even hostile to any agitation or legislation which rests upon the acknowledgment that the disease is prevalent among them. Even the local boards of health, which should be foremost in public health work, take but little in-

terest in the problem and view with indifference the customary laxness of the medical profession in diagnosing and reporting cases of the disease.

Under such conditions the first step in educating is to convince the people that tuberculosis exists in their particular community.

When the local association was formed with which I had some acquaintance, a supposedly well equipped physician said to me, "What is the use?—there are no consumptives in this community." When I showed him that nine deaths from the disease stood on the town records of that year, he could only take refuge in the assertion that the diagnoses were incorrect. Let it be admitted that sometimes even in the medical profession we find bliss and ignorance combined.

To undertake the work in rural communities it seems wise to begin with a thorough understanding of the problem. Nothing can help so much as to empower the State Board of Health to make an accurate survey of rural tubercular conditions. This cannot be done without the appointment of additional helpers. It seems wise to urge the necessity of the appointment of a nurse in each health district who shall work in harmony with the health officer. With such an increase in his staff, it is thought that our competent Commissioner, Dr. McLaughlin, will be able to collect the facts which will lead to a proper understanding of the problem and eventually permit of the control not only of tuberculosis but of other communicable diseases. It seems to be our duty so to influence legislation that our commissioner will be able to carry out this prospective survey.

Let the anti-tuberculosis workers of the state advocate wise legislation, but let them also encourage and take active part in the formation of anti-tuberculosis associations in our smaller communities. That there is plenty of opportunity for this work appears from the statement, based on credible information, that in towns of less than 10,000 in our Commonwealth, there is only one active anti-tuberculosis association. Associations which take up their duties in smaller communities can do very effective work by co-operation with all the allied agencies so that in that Utopian day when the State Department of Health assumes complete control of the work, they will find preparation has made their task easier.

A most efficient method must be by the establishment of these branch organizations which coöperate with the National and Massachusetts Anti-Tuberculosis Associations. The day of the local anti-tuberculosis association has not passed. Its duties are just beginning in these rural communities and we can but hope that many modest but active associations will soon come into existence, doing their work as nobly and as effectually as those of the cities.

The review of the annual report of a well organized anti-tuberculosis association in which

attention is called to the prominent citizens on the board, the expert physicians who advise the corps of trained nurses, the well equipped hospitals, sanitarium and dispensaries, is depressing for the would-be worker of the rural community. It is easy to succumb to discouragement and quickly acknowledge that with the scanty talent at hand nothing can be accomplished.

In the fight against the white plague there is no room for such pessimism. No one can read Trudeau's Autobiography without being impressed with the optimism which he preached and which mastered him, and no one can claim such isolation that nothing can be accomplished in his hamlet. May many a neglected town develop workers with a Trudeau-like spirit! Although their names may never be acclaimed like his, their opportunities in the service of mankind promise much more than he ever dreamt the primitive lumbering camp of Saranac held for him.

The consumptives of a rural community will vary according to the population but they will seldom be numerous; and the smaller the town, the fewer will be the patients accepting charity. Sociological questions will be such as to make few exacting demands upon the officers, and many workers will not be needed; but a few workers can accomplish much. An interested physician is indispensable and, if the community is large enough, a trained nurse may be well employed in the field. In the larger towns all of the nurse's time may be needed, but it is more likely that it will be found wise to employ only part of a nurse's time in the smaller towns. In this case a convenient arrangement can be made with the local charity organizations, the nurses' associations, the Foresters, the churches, or other interested societies.

The object of the newborn organization should be to maintain a central organization for keeping information about tubercular patients,—to keep in touch with these patients, referring them to sanitarium if necessary and to keep acquainted with patients who are sent to the community from sanitarium.

The other duties, which are axiomatic, will be omitted before this audience, so well educated in tuberculosis work.

As the years go by no earnest worker in rural communities can fail to be convinced that he has a large educational opportunity, and as his experience increases he will find that where the field of social service is limited, the main function of his organization must be educational. There are plenty of opportunities to give talks before granges, churches, Foresters, etc. It is disappointing to find the school children are not given the privilege of instruction in tuberculosis, although the laws of the Commonwealth particularly prescribe it. It appears to be the duty of the local anti-tuberculosis association to see that instruction is given in the nature and prevention of tuberculosis. One of the methods easily adopted is by means of the set of lantern

slides which are supplied by the National Association and are accompanied by a regular printed lecture which can be amplified if desired. The talk of about twenty minutes and the pictures never fail to make an impression and can be used for children in the higher grades, whereas simpler exhibits can be easily secured to vary the instruction. When talks are given the opportunity should never be neglected to give printed pamphlets to the children, who eagerly accept them and carry the message to the home circle. The superintendent of schools will gladly give the speaker the opportunity to talk, for it relieves the teachers of instructing on a subject upon which they feel ill prepared.

Moving pictures have been used with great success in some communities. It takes little effort to arrange for a complete program of films furnished by the National Association. By co-operation with the local movie manager tickets for all the children in the upper grades can be secured at a moderate price, and while enjoying a treat, the school children obtain lasting impressions.

Our main hope in this campaign is in the children of today who will be the workers of the next generation. May they be properly acquainted with the great facts which our generation missed! It is our duty to see that heredity as a factor is entirely erased from the black board and that the individual unit will not endeavor to blame his prenatal condition for his unhealthy state. It is our assurance that education of the school children of today will do more to cut down the number of consumptives of twenty years hence than any other factor. Let the tuberculosis worker of the rural community pound in these facts if he neglects all others and he will have accomplished much.

We must spread broadcast, by whatever means we have, the fact that "tuberculosis is a song begun in the cradle of the infant." The child is the beginning and the solution of the anti-tuberculosis problem. We may be too late to save the diseased of the present generation, but if the children of today are taught what we wish them to know, the devoted fathers and loving mothers of another generation will see that their offspring is protected even if their lives have paid the price of ignorance.

With the children, education appears to me as the most important aspect of the problem, for they are easily reached and they are the future. I would suggest that the State Board of Health take upon itself the duty of securing that the present laws in relation to the education of school children are enforced.

There is a great deal to be said for the tuberculosis problem with children. It is a problem which should be given the most careful consideration, and that the State Board of Health should take upon itself the duty of securing that the present laws in relation to the education of school children are enforced.

said about the characteristics of the disease it causes, until now a few of the laity appreciate some of the essential facts which have been driven home by such interested people as present themselves here today.

There is another type of bacillus, however, namely, the bovine type. It is well known to bacteriologists and specialists upon the subject of tuberculosis, but this germ provokes little interest from the majority of the medical profession and the laity.

The bovine type of germ is purveyed to inhabitants of city and town alike by the farmers of our rural communities. If the inhabitants of Massachusetts are not well instructed in regard to the old fashioned type of pulmonary consumption, they certainly need instruction in regard to the tuberculosis which is caused by the bovine type of bacillus. The evidence against the bovine bacillus has accumulated at a rapid pace and it is time some steps were taken to guard against it. It infects adults and children, but as the germ is carried to us chiefly in the milk, it is not strange that the milk consumers, and particularly the children, are affected. The children under five years are the chief sufferers, be they residents of city or country. This is a menace to the children of the city as well as the country. Any rural anti-tuberculosis worker must hail the day when a regular campaign of education is begun in regard to the dangers of milk from tubercular cows. The entire state is aimed against and the rural communities are the sinners in producing the infected milk.

The results of individual investigators, as well as the British Royal Commission on tuberculosis and the German Commission, show that there is a considerable percentage of bone, joint, abdominal and lymph gland tuberculosis which is bovine in origin. By far the most convincing work on this subject comes from Park and Krumwiede of the Research Laboratory of the New York City Board of Health. They have themselves studied 478 cases and, after adding the cases observed by others, their tables show altogether 1,511 tuberculosis cases. After tabulating and reviewing the subject they conclude 12.5% of fatal cases in children under five years were due to bovine infections, while in the total series about one quarter (26%) of all the cases under five years were bovine infections.

This paper is not strictly scientific and the writer must be excused if he fails carefully to quote all the investigators who have become convinced of the danger from the milk; but it seems wise to mention a few suggestive references.

Orth says 10% of all tuberculosis in children is due to bovine infection. An English observer says not less than 25% of the tuberculous children under five years of age suffer from an infection of bovine origin. It is possible to quote many authorities for the accepted fact that a great deal of tuberculosis in children is due to milk from infected cows. A. Stanley

Griffith, in a study of tubercular cervical glands, showed that the proportion of bovine infections reached as high as 90% in the children that he examined under five years of age.

It is not wise to trespass upon the ground of the veterinarian, but it cannot be doubted that there is a great deal of tuberculosis in the dairy cows of the United States. Chief Melvin, of the Federal Bureau of Animal Industry, and Professor Moore, of Cornell, concur in the opinion that not less than 10% are affected.

In our own state, between 1893 and 1908, 10,688 were found to be tuberculous by the tuberculin test, as well as at post-mortem examination.

A. P. Mitchell of Edinburgh, in a study of the frequency of bovine tuberculosis in cervical adenitis, found out of seventy-two cases sixty-five yielded the bovine variety and only seven the human type. He was not surprised, on making an examination of 406 samples of milk collected from as many shops of his Scotch capital, that 20% of them contained the germ of bovine tuberculosis.

The Department of Health of New York City examined 78 samples of milk, 11½% of which showed virulent tubercle bacilli.

Unselected raw milk, taken at random from various cities, show virulent bovine tubercle bacilli in from 10 to 20% of the samples.

There appear to be two ways to do away with the danger of infected milk. First, do away with all infected cows. There is no time to go into details in discussing this impossible procedure. Science and economy would not favor such wholesale slaughter and it is not for us to urge such foolhardy legislation upon the state.

A more practical method is offered in the pasteurization of all milk—a measure which our State Board of Health heartily favors. This process does away with the danger of other infections than tuberculosis and, while being a good hygienic measure, is the most economical and surest way of removing all danger of the transmission of tuberculosis through milk.

#### SUMMARY.

1. Rural communities are very ignorant of the prevalence of tuberculosis.
2. Rural communities have been neglected in the anti-tuberculosis campaign.
3. The formation of anti-tuberculosis associations should be encouraged in such communities.
4. The State Board of Health should be encouraged to make a thorough survey of the prevalence of the disease.
5. The State Board of Health should enforce the law which demands instruction about tuberculosis in the public schools.
6. Instruction is needed in regard to bovine tuberculosis.
7. Bovine tuberculosis is commonly conveyed through the milk and is a menace, particularly to children under five years of age.
8. There should be a state law compelling the pasteurization of all milk.

## SOME PROBLEMS OF THE TRUSTEES OF MASSACHUSETTS HOSPITALS FOR CONSUMPTIVES.

BY ARTHUR K. STONE, M.D., BOSTON.

A GREAT ray of sunlight has come to us who have been combating the almost insuperable difficulties surrounding the tuberculosis questions, in the report from Australia of a fall in the death rate to 8 per 1,000 and of the practical disappearance of the tuberculosis question in Victoria.

Even should this latter report be premature, nevertheless, the fact that it can be made by a man of the standing of Dr. Heiser shows that efforts which have been put forward and pushed in spite of failure, mistakes and hostile criticism are along correct lines, for the Victorian victory is but the triumph of segregation and isolation of the patients with this disease.

This gives us here in Massachusetts courage to go ahead and press the laws which we have on our statute books, and should encourage every worker in the individual societies, which make up the League, to work with redoubled energy—not flagging zeal—to spread the health education from the so-called intelligent classes to the most needy and ignorant persons in our midst, always remembering that the well-to-do persons are often the most ignorant.

First of all, let us do what we can to help out the laws which have been proposed to provide hospital accommodations for all who wish and need the protection of the hospital for themselves and for the good of their families.

Let us show to our friends in the legislature the needs in every town, so that we may have the necessary places for segregation of the active tuberculosis patient. Then when that has been accomplished, the dispensaries will begin to pick up the early and suspicious cases and transfer them at once to Rutland and the other sanatoria where the chance of arresting the disease is greatest.

The plans for the general segregation and treatment are complete. They have not as yet been carried to the fulfillment and cannot be for several years to come, under the most speedy conditions. But the fulfillment of the plans can be but a matter of time. Brookline has built a charming little hospital. The Barnstable County Commissioners have been studying their problem. Lowell has selected its site and—this settled—must soon take itself out of the group of laggards. New Bedford will soon increase its facilities—the energetic Mr. Geoghegan assures us—and put itself still further in the lead of all the Massachusetts cities. Malden for the moment is held up by a new mayor. Fall River will build a hospital commensurate to its needs and not be content with one of about one-third the proper size. All this is of the greatest encouragement and gives promise of greater advances in the future.

The move made by the State Board of Char-

ity to raise its payments for state cases from \$7 per week to a sum nearer to the actual cost of maintenance in the various local hospitals will do much to diminish the discount which one finds cropping out regarding so-called state cases.

There is earnest work in all directions being done by the Department of Health and there is the fullest cooperation of that Department and the Trustees of Hospitals for Consumptives, this cooperation manifesting itself in the constant courtesies between the Inspectors of Health and the physicians in the districts and our after-care worker, who does much to help them in many outlying districts; and on the side of the towns and cities, the dispensary nurses are helping and taking the burden from our after-care worker in many communities; and doubtless the time will not be far distant when other cities and towns will be able to report all that she wants to know by the mere writing of a letter.

But although much in the way of cooperation has been accomplished, there are still communities where the idea of getting in step and making a mighty effort to get the upper hand of the tuberculosis problem does not seem to have penetrated. There are boards of health who seem to prefer to see how little they can do, who will not acknowledge that they have any tuberculosis to deal with; who only know those few cases reported by physicians and who make no attempt to have all cases reported; who point with pride to an unsuccessful clinic and who seem to gloat if they can find an advanced case that they can force upon the state sanatoria. A few boards have all of these uncoöperative tendencies—and many more develop some one or two of them. The point of view of the state policy is misunderstood and opposed. That there are reasons for such misunderstandings, I can well appreciate, but I know that every one in the Hospital Department and in the Department of Health and in the Board of Charity would be willing and glad to talk to any disgruntled and perplexed individual to try to smooth out these difficulties; and with a little more cordial getting together many of the misunderstandings can be done away with. So when you, as workers in the cause, hear of misunderstandings, urge a personal interview and see if the matter cannot be straightened out.

A perpetual problem for the Trustees of the Hospitals for Consumptives is the difficulty of administration. In the four sanatoria are gathered together a thousand patients. Gentle and Jew, white and colored, and native and foreign born, even to the dwellers of China and Mesopotamia, united in the common belief that they are the victims of the terrible tuberculosis, and must die.

It is not to be wondered at that many of the patients are honestly often uncoöperative, and even rebellious. Their manner of life has been dominated almost entirely by science and they

are expected to conform to institution rules and regulations which should be strict so as to secure for the patient the greatest chance for recovery and return to economic usefulness in the shortest possible time.

The response of the patients to hospital life is very different. The great majority say that they wish to get well and they think they mean it, but in spite of this many of them drift into the indifferent class, apparently quite content to eat and sleep, and beyond that to do little to help themselves or their neighbors to improve. This group of seemingly indifferent people are a great drag on the medical staff and upon those patients who are zealously trying to return to health and work. The boundary line in this group is very indistinct and many would be surprised to be considered therein. Some are only there occasionally, sliding down in a fit of the blues, while at the other end, a few drop down from the indifferent group into the undesirable class; that is, the group to whom all rules and regulations are anathema and their whole attitude is one of opposition to authority.

We have to take the men and women as they come, with various undesirable habits fastened upon them, and they do not leave these at the doors of the institutions. Some of these habits have been a factor in their undoing and falling a victim to the bacilli of tuberculosis—but by them this fact is usually not recognized.

With this heterogeneous mass of patients the institutions have to deal. The work is for a great part educational, trying to show why the rules and the regulations are made and why their enforcement is necessary. The coöperation that is secured between the staff and the patient has to be founded on intelligence and not on discipline, and yet there must be a line where forbearance and patience cease to be virtues and discipline must be maintained. For the intractable group of patients, of whom there are many in the community, and the Boards of Health are in touch with many more of them, because only too often they will not enter voluntarily any institution—there must come some place where these persons who are a menace to the community can be segregated; where they will be under control as menaces to the public health and not allowed to endanger the wellbeing of others. This to my mind must follow quickly on the establishment of all the necessary local hospitals that are now planned. It is, however, to be hoped that with the spread of education and temperance reform, and other uplift work, that this group may grow so small as to become a negligible factor in the tuberculosis campaign.

It is to my mind a debatable question whether the state should build a new institution to which should be sent the intractable and indifferent patients and those state cases which do not belong in the Tewksbury group and for whom there is no provision in the local hospitals, or whether one of our present institutions can be enlarged

to advantage so as to take care of these cases and to use the other three for the really early and curable cases.

Again, what is to be the future of the work for children? The start at Westfield is most encouraging. Is it to be developed then to the exclusion of adults and will this very growth among the children make a new state institution necessary?

These are perplexing questions which I find it difficult to answer, practically impossible of answer until the new hospitals are in full working order.

In a recent bulletin of the New York Department of Health the statement is made that the nurses of the department were finding five cases of tuberculosis for every death reported. The Industrial Accident Board are having cases of tuberculosis put up to them as industrial accidents and there are judicial decisions which make it possible that such claims may be allowed. If that is so the employers of labor will have to protect themselves by physical examination of their employees, and there will be a demand for sanatorium treatment of many very early and suspicious cases such as never before has arisen. Are we as yet, in our plans, even prepared to meet this probable demand for early sanatoria treatment?

In New York City there has been such pressure for beds for active cases that we are told that patients are discharged who have a certain number of negative sputum tests. This is an entire abandonment of all attempt of cure for purposes of segregation. The emphasis is put on the community at the expense of the individual. This extreme position does not seem to me justified; persons with tuberculosis should be segregated, it is true, but, if possible, they should be cured and returned to the community, able to be useful citizens once more. Arrest of the disease and return to economic usefulness should be the purpose of the state in its work as well as mere segregation.

Nevertheless, there are a number of patients who, after a period of progress, seem to come to a standstill, or the progress is very slow, indeed. Some, though this active progress is arrested, show that they can never become self-supporting, active citizens again. They can live—and live happily—under the protecting walls of an institution. Some of these persistently have bacilli and some never have bacilli or, at most, at rare intervals.

What shall be the attitude of the state to these persons? In the course of years, groups of this class of patients tend to collect at various institutions. What shall be done with them? To this group must be added the group of patients where, in spite of marked symptoms and signs in their lungs, there is nevertheless grave doubt whether the process is even that of real tuberculosis, but rather of so-called chronic bronchitis or bronchiectasis. These people are sick and suffering, but they are not,

Massachusetts says shall be done. This minimum is in the statutes, the laws relating to tuberculosis. To create hearty opinion in favor of these laws is a fundamental part of any program. It may be the law relating to a hospital, county or otherwise; to a dispensary, or to examination of school children, or giving information about tuberculosis in the school. Are all four laws carried out? If not, why not? All that you have obtained in the way of facts from your study of individual families cared for by other agencies or your own, use to show the need of law enforcement. Always—"When in doubt, trumps." Education is the "trumps" of the tuberculosis campaign. Public opinion we must have. Use your facts to make people care and to make them work. It is interesting that in the morning program the boards of health gentlemen talk, so they are here; in the afternoon they are not on the program and I am afraid they are not here, Mr. Chairman. I am sorry, because we are going to talk a little about them and it is so much pleasanter to do it in their presence. One question that was emphasized this morning was the need of complete harmony between the tuberculosis association and the local board of health. I should think that complete harmony, absolute harmony, would be possible under two conditions: One where you have two progressive groups, each of a high standard of efficiency, having vision, with a common understanding of the problem and much respect for each other, going ahead without jealousy, without friction, with continuous coöperation, and discussing matters and together evolving action so that it is hard to tell who was really the initiator of this policy or that. The other instance of complete harmony would seem to be where you have two equally inactive bodies. Very often, however, you have one active body and the other inactive. The inactive body may be either the tuberculosis association or the board of health, but when the situation exists, ten to one, each thinks the other more than a little queer. Then there is lack of complete harmony, but it seems to me that a community in that situation is much better off than one where there is absolute harmony and united inaction. I am just as ardent an apostle of coöperation as the preceding gentlemen, but I am no believer in coöperation in inactivity. I think that a good solid, impersonal fight, with an awakened public to judge between us, is more effective for the prevention of tuberculosis than where the lion and the lamb are lying down together peacefully asleep.

To return to our program. What more shall it include? Added to the enforcement of the laws of the State, there is the open-air school program, of which mention has been made so often at your meetings. On the educational side there is the work referred to here this morning,—the work of getting the facts as they are, whether they come from our own streets, from New Zealand or Australia, before the public, whether

in the form of a pamphlet, a leaflet or in moving picture. The gentleman from Haverhill said we do not all speak the same language. In addition to the use of the foreign press, we may be able to teach parents through the children as is now being tried in New York, where the school board has given hundreds of thousands of pamphlets, on how to reduce the cost of living through careful buying and good cooking.

One method of education where I think we have been singularly lax, is in not making a great deal more use than we have of our cured cases. We might all take a lesson from the temperance platform, where the man who has been reformed comes and talks to the people. We have plenty of patients who have been cured. In our chairman's address a year ago, he told of a teacher who had been cured and able to continue teaching for seventeen years. That teacher, who had tuberculosis, who has since been teaching for seventeen years, on your movie stage or on your speaking platform, could do more to make patients willing to go to a hospital and give the public an appreciation of what hospital care means, and prevent hysterical fear of arrested and cured cases, than any one of us here. Especially in educational work for different nationalities, a cured person of that nationality, even if he is not a "speech-maker," his presence at a meeting where his countrymen can see him cured and working again in their midst, is in itself an effective object lesson.

Again, what shall our program be? Some of you are conducting hospitals, some of you are maintaining dispensaries; most of you who are doing that work are doing it so well that it is a very difficult and capacious thing for anyone to criticize. But remember that just so far as institutions have their dangers, those dangers apply to you. I mean by their "dangers" their very virtue, their very efficiency, their very seeming adequacy. Here you have a well-run institution, and that is a real achievement; what strength have you left for your work outside the institution? You exist first as an association to prevent tuberculosis.

It was stated this morning that the State has called upon your board of health actually to do those things; the Commonwealth has legislated that your board of health shall maintain your dispensary and shall conduct your hospital. You do it, some of you say, because you cannot trust your board of health. It seems to me that the work that the board of health does in tuberculosis is a barometer of its general work. I understand that a barometer does not mean that it always rains when it says it will, that there are exceptions. Therefore I do not choose the thermometer which is an exact register. Please note the difference. I understand there is a board of health represented here that does excellent work in everything except tuberculosis. I know one tuberculosis organization here that has said it could not hand over to its board of

health the splendid institutional work it was doing because it could not trust the board of health. Not long ago that very board of health was startled to find that a case it had diagnosed as chicken pox was in fact smallpox, and the delay of the health board in following the diagnosis of others was extremely disquieting. You are trusting your board of health with life and death every day; so when you take away from its care this special form of life or death, do not forget you are leaving it with the great responsibility for the health of your citizens. It pays to go behind the apparent necessity of doing this or that thing yourself, because you cannot do the whole thing yourself. A big part of your job is to make the public realize that the whole health work has to be done well. I know places where at this moment, if I were a trustee of a hospital, I should hate to hand it over to the public body; but I hope I should have courage to say why, before every election, and work hard to get a board of health I could trust. There are boards of health we all respect and fully trust and we must work to multiply their number. Why do some of you who are doing these tasks of the board of health give up the educational campaign? I asked Miss Acton—you know her paper last year was really a mirror of our actual doings—what effect it had, and she said, "So little that you can say it all over again if you want to." She thinks one reason why you do not care for an educational campaign is because you cannot get the money to carry it on. Then tell the public so. Tell the public of the division of work between the public and private agencies indicated by the statutes. Then ask for the money for the much-needed educational work, but don't think you can't get the money until you have tried.

I know a certain district where the death rate from tuberculosis is very high, and where the number of saloons to the population is also very high, and where the housing conditions are extremely poor. At a meeting of the doctors and teachers and representative people, generally, these things were admitted. Then the question came, "What will you do about it?" "Well," they said, "we know the people who own the houses, we went to school with the men who run the saloons; let us ask the city to give us another nurse."

That, ladies and gentlemen, takes us back to a story so old that the only excuse for repeating it is that the situation it fits is still with us. You remember the story of the town that had a precipice. The people used to fall over the precipice, and had to lie bleeding and injured, perhaps for a long time, until somebody came along and took them to the hospital; so the town selectmen met one day and voted that they should have an ambulance wait at the foot of this precipice in order to carry people to the hospital more promptly. It was many years before the town voted to put a fence at the top.

That story is old, but we haven't built that fence yet.

To just simply nurse—it is splendid; but it is having a fire engine without any campaign of fire prevention. It is trying to put out the fire after it has started. It is palliative. It is deserving of all those words that socialists hurl at us. We must get behind to the real facts and causes and the prevention of them. And that must be, it seems to me, the main part of our program; or, if not the main part, at least an always present part. Begin with this essential part of the program, and add to it what you will. Get the facts of your town or city; bring those facts home to the people in every way that ingenuity and love can devise. You are the interpreters of this great pitiable, preventable thing. You remember Trudeau said, "Pity as an emotion passes, but pity as a motive remains." We all should see that this pity in our hearts remains as a motive to bring the story of the suffering we know so intimately to our public constantly; not only in an appeal for more nurses to take care of the people who are sick, not only for hospitals to segregate all the people who are dangerous, but above all to do these things,—prevent danger and prevent disease.

Just in closing, let me repeat a story, for sometimes a story recalls the moral. A lady and her pet dog started on a journey. The lady was fond of the dog and insisted that he should ride with her, but the conductor said that the dog must travel in the baggage car. She said, "Oh, dreadful!" And he said, "Oh, well, I will take him in." But she said, "No, I will take him in myself." So she carried him to the baggage car and tied him up herself. Some time later she asked the conductor, "How is my dog getting on?" "I don't know, madam," he said, "you tied him to a trunk, and the trunk was thrown out at a station fifty miles down the line."

Be careful what you tie to. The most essential thing of all that we should tie to in the whole tuberculosis work, splendid and necessary as all those curative things are, is the great campaign of education which spells prevention.

## ANNUAL REPORT OF THE SECRETARY, MARCH 31, 1916.

### Membership.

At the end of the first year thirty-four organizations were members of the League. At the end of this, the second year, four more have been added to the membership, making the Report instructive. District Nurses' Association, the Middlesex District Nurses' Association, the Leicester Sanitary Society, and the Middlesex Anti-Tuberculosis Society. The total number of schools, churches, and organizations, however,

of two older tuberculosis organizations. These additions bring the membership of the League up to thirty-six, and an effort has been made during the year to have organized anti-tuberculosis work started in several other communities.

### *New Offices and Equipment.*

In February the League and the Boston Association for the Relief and Control of Tuberculosis moved their offices from 4 Joy Street to 3 Joy Street, where they now occupy a larger suite of rooms all on one floor.

A Special Committee, authorized for the purpose by the Executive Committee, has conferred with the Boston Association on the matter of running expenses, with the result that the League is now paying a portion of the rent of these offices and a share of the salaries of the workers. The League has also joined the Boston Association in purchasing a safe, while for its own use it has bought a typewriter and a Parcels Post Exhibit. Through the kindness of the Treasurer and the generosity of the Duthie-Strachan & Company, Inc., a simple system of bookkeeping has been installed.

### *Legislation.*

At the time of our last annual meeting the Legislature was still in session, and it was therefore not possible to make up a final report on the twenty-three bills considered by the Legislative Committee of the League. We can now report that of the twelve bills approved by the League, seven became law, the others being rejected by the Legislature. Of the eleven bills upon which the League took no action five became law and six were rejected.

This year the Legislative Committee has considered forty-two bills. Thirty-two of these have been approved by the Committee, no action being taken on the other ten. The Legislature is still in session, so that it is again not possible to make a final report as to the disposition of the year's legislative bills.

One matter that has been discussed at some length by the Executive Committee, and upon which educational work is undoubtedly needed, is the failure on the part of physicians and others to report cases of tuberculosis, as required by law. A reference to the report of the Recess Committee on Tuberculosis shows that in almost one-fourth of the cities and towns in the state those responsible are exceedingly negligent in this direction. Unless we can enforce the good laws already on the statute books, no amount of new legislation will avail.

### *Red Cross Christmas Seals.*

The accounts of the sale of Red Cross Christmas seals are now all in except from one city, and we are glad to report that 2,231,877 have been sold. This is a gain over last year of 403,895. These seals were sold by one hundred and thirty agents, eighty-five of whom were

Anti-Tuberculosis Societies, District Nursing Associations, Associated Charities, Boards of Health and Women's Clubs. This figure does not include the hundreds of stores, banks, clubs and individuals who sold seals for the agents.

Ninety per cent., or \$20,086.88, is the amount from the sale of seals secured for tuberculosis work in this state. Deducting from this \$586.37 (the amount of expenses incurred in the sale) as reported by the various agencies, we have for use in the state the sum of \$19,500.51.

Seven and one-half per cent. of the proceeds, or \$1,931.48, is for the use of the League, and after deducting the expenses of the League, such as salaries, printing, postage, express, etc., which amounted to \$327.97, we find that the League has a balance of \$1,603.51 to be put into anti-tuberculosis work.

### *Publicity.*

Under the head of publicity we include lectures, and the use of films and slides, and the printing and distribution of literature, such as legislative bills and press bulletins.

### *Literature.*

A circular entitled "Is the Work of the Anti-Tuberculosis Society Finished?" was printed, and about nineteen hundred copies of it distributed. This circular stated in very positive language the continued need of Anti-Tuberculosis Societies as long as tuberculosis exists. The strength of the circular was emphasized by the fact that it was signed by the State Commissioner of Health, the Chairman of the Massachusetts Trustees of Hospitals for Consumptives and the President of the League.

Nine hundred copies of the annual report were sent out, and twelve National Association Press Bulletins, or a total of thirty-three hundred copies, were mailed to two hundred and seventy-five newspapers throughout the State.

One hundred and twenty-five copies of miscellaneous leaflets, some of which were supplied by the Boston Association, were distributed. This literature, with the three hundred and thirty legislative bills, one hundred circular letters on legislation, and letters urging social agencies of various kinds to do all possible to popularize the tuberculosis dispensaries, brings the total distributed up to about 6,655 pieces.

### *Lectures.*

During the year fifteen talks, fourteen of them by your Secretary, were given on Tuberculosis or Open Air Schools in the following places:—Attleboro, Beverly, Braintree, Brookline, Danvers, Framingham, Lynn, Malden, Medford, Provincetown, Quincy, Scituate, Ware, West Newton, and Weymouth, with a total attendance of about three thousand persons.

### *Slides and Films.*

Many of these talks were illustrated with slides loaned by the Boston Association, and on

ical work. Almost on every page the author bewails his lack of familiarity with the practical side of illness, and the slight amount of practical work done in medicine and surgery before a medical degree was obtained. It would be inconceivable to a recent graduate of a good American school that a man could be a full-fledged physician, even without a hospital appointment, and feel so utterly at sea in regard to the common procedures of practical importance as our author does.

It would seem likewise to most American physicians, that the author takes too gloomy a view of the attitude of the patient's family towards the physician in cases that were of extreme severity or ended unfortunately. He graphically describes this in telling of his experience in treating a child desperately ill with pneumonia. He says, "In fact, without seeing the patient, I always unerringly guessed how he was by the expression of Katerina Alexandrovna's eyes, when she opened the front door; if he were worse, her face breathed ill-concealed dislike, if he were better, her eyes beamed on me with infinite tenderness." Probably all physicians have experienced similar occurrences; some families can never forgive the physician who finds out that there is some serious or fatal malady afflicting those that are dear to them. Few medical men will read this book without recognizing some of their innermost thoughts, their fears, doubts, and anxieties in the early years of practice, though it is probable that few have such a pessimistic view of what, after all, are but incidents common to medical practice.

*The Practical Medicine Series. Under the General Editorial Supervision of CHARLES L. MIX, A.M., M.D. Vol. viii. Materia Medica and Therapeutics, Preventive Medicine, Climatology.* Edited by GEORGE F. BUTLER, Ph.G., A.M., M.D., HENRY B. FAVILL, A.B., M.D., and NORMAN BRIDGE, A.M., M.D. Chicago: The Year Book Publishers. 1915.

This eighth volume in the Practical Medicine Series for 1915 deals compactly with the subjects enumerated in its title. The section on materia medica and therapeutics, which constitutes more than half the book, is divided into three parts, dealing respectively with drugs (the therapeutic agents being alphabetically arranged), with extracts of animal organs, bacterial therapy, sera and vaccines and with electricity, Roentgen rays, radium and radio-active substances. The section on preventive medicine by the late Dr. Favill deals with the physician in public health work, with the infectious diseases, with school children and contagious diseases, with industrial and social diseases, with general sanitation and with eugenics. The brief section on climatology by Dr. Norman Bridge deals with certain aspects of climate and dis-

ease. Though somewhat miscellaneous in its content, the volume is of definite value in completion of the admirable series of which it forms a part.

*Infections of the Hand. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm.* By ALLEN B. KANAVAL, M.D., Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Third edition, thoroughly revised. Illustrated with 161 engravings. Philadelphia and New York: Lea and Febiger. 1916.

The present edition of this well-known book is to be welcomed by the entire surgical profession. The form and outline are unchanged, but certain additions have brought the number of pages up to 500. There are two new chapters: The first, "Relation of Acute Infective Processes to Industrial Pursuits," by Dr. Harry E. Mock; the second, "Plastic Procedures Instituted for the Correction of Deformities."

Dr. Kanavel's book is practically beyond anything except the most favorable criticism. To each of the more extensive of the 29 chapters, he has added a brief résumé. If it were not for this, one might possibly feel that the book is a little too long; that 500 pages upon infections of the hand alone might be apt to keep the average student from that very thoroughness of study upon which Dr. Kanavel properly insists. A careful examination of the book, however, shows that it covers, for all practical purposes, not only infections of the hand, but also infections of the forearm. Furthermore, the statistics from industrial sources show not only that infections of the hand are extremely common, but that their sequels are very serious and together they form an unexpectedly large proportion of the disabilities due to accidents in the working classes. When these two facts are considered, together with careful records of cases and their final results, it becomes evident that the book is not too large.

Dr. Kanavel brings to his task enthusiasm, enormous industry, careful observation, extensive clinical experience, anatomical investigation, and finally, the follow-up system, which, taken altogether, make his book an ideal one-man treatise.

The question which sometimes bothers the reviewer brought face to face with the steadily increasing number of textbooks, "why was this textbook undertaken?" can never arise in relation to this volume. It was undertaken to add to the existing knowledge of an important aspect of surgery, and it has been most successful in achieving this end.

Every advanced student and every surgeon should have it close at hand.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, OCTOBER 12, 1916

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## INDUSTRIAL HEALTH INSURANCE.

THE brief for health insurance, published in this number, may well be called timely, in that the matter is one on which medical men should be informed, whatever their attitude as to the desirability of such form of insurance. This is particularly important in view of the fact that if such insurance is to come, it is incumbent on the profession to see that its own rights and privileges are not too much abridged. There is an advantage in working under an insurance act, because payments are assured, and not at the whim of the wage-earner, as is so often the case today. There is, however, a danger that compensation will be placed too low; a still greater danger that the administration of the act will make the practice of medicine in industrial communities far less comfortable and satisfactory for the doctor, and the relation of patient and family physician is necessarily going to be somewhat modified and interfered with.

A committee of the Massachusetts Medical Society, appointed last June, has been working with this end in view. If such legislation is to be passed, it is essential that the medical side of it should be considered. Mr. Andrews' communication tacitly recognizes that there is a medical side, but pays no attention apparently to the necessity of considering this side. The danger in any legislation of this sort is that the economic theorist figures on the broad principles involved and is likely to seek legislation along the lines of the best broad theory, without stopping to figure who is hit or how the people, who have the work to do, are going to be helped or hindered in doing it.

It is just for this reason that it is important not only that there should be a committee, but that the mass of the profession as a whole should be informed and ready to do what they can to see that no mistakes are made. This is true whether the individual thinks that this sort of social insurance is moving in the right direction or not. Those who are best qualified to judge seem to feel that some legislation of this sort is bound to come; perhaps not this year, but within a few years. If the medical profession do not look out for themselves in the matter, it is pretty certain that no one else will look out for them.

## THE RÔLE OF THE STATE TUBERCULOSIS SANATORIA.

THE word "sanatorium" coming from the Latin *sanare* (to heal), implies that at such an institution active efforts are made to cure, or at least to arrest, the disease. It is, likewise, proper to infer that at a real sanatorium only those patients are admitted who are in the curable stages of the disease and who offer fair prospects of permanent arrest of the pulmonary process.

Ever since its foundation, the Richard State Sanatorium has been reserved for patients in the early, favorable and unprogressive stages of the disease. Patients who are in the advanced stage of the disease, or in the process of relapse, are not admitted. The medical staff of the sanatorium is composed of a large number of physicians, and the treatment is of the most modern and scientific. The sanatorium is situated in a beautiful spot, and the climate is ideal for the treatment of the disease. The patients are given the best of care, and the results are most satisfactory. The sanatorium is a place where patients can find rest and recovery, and where they can be cured of their disease.

this period. If, at the end of this time, he is found to be in the advanced or progressive stages of the disease, or in any other ways, he is not considered a suitable patient for this particular institution, he is transferred to another sanatorium or sent elsewhere. Thus the condition of affairs, as far as the Rutland State Sanatorium is concerned, although not yet entirely satisfactory, is at least fairly so, and one that is constantly improving.

This is not altogether the case with the three remaining State sanatoria, at North Reading, Lakeville and Westfield. In many ways these three institutions, which were opened in the years 1910 and 1911, are vastly better suited for the care and treatment of patients in the early stages of tuberculosis than is the case at Rutland, which was built in 1898. At the time they were opened, however, the incipient consumptive could be cared for fairly well at Rutland, while there were practically no accommodations for that most pathetic and dangerous of cases,—the advanced consumptive. As a result, beds at these newer sanatoria were at once filled with patients, most of whom were in the advanced stages of the disease. It was not intended by the Board constructing these three institutions that they should be homes for advanced and incurable consumptives; yet because of certain unavoidable circumstances which led to the immediate admission of many patients of this class, they have come to be looked upon as places where patients in any stage of the disease can go and receive treatment. This is an unfortunate state of affairs, and one which, to a large extent, defeats the very end for which these sanatoria were planned.

At the present time, there is a large number of beds in local tuberculosis hospitals intended for sick and advanced consumptives, while, in addition a bill has been passed and definite appropriation made for county tuberculosis hospitals, which will provide beds for those communities without local tuberculosis hospitals of their own. There would seem to be, therefore, no reason why the North Reading State Sanatorium, the Lakeville State Sanatorium, and the Westfield State Sanatorium should not fill the rôle for which each was originally intended, *i.e.*, an institution where tuberculous patients in the curable, though not necessarily incipient, stages of the disease could receive active and aggressive treatment. At these institutions no line is drawn at the word incipient. At Rutland every

effort is made to admit only those patients who are really in the first stage. At the other sanatoria, this distinction is not drawn, the sole qualification being that the patient should be considered capable of ultimate arrest or, at least, of marked improvement.

It is to be hoped that the medical profession of this State will realize the wisdom of this viewpoint, and will coöperate in every way with the superintendents of these institutions and the board of trustees, so that municipal and county tuberculosis hospitals will be used more and more for the advanced, progressive and dying consumptive, leaving our four State sanatoria to play the part in the tuberculosis campaign originally assigned to them.

### PROGRESS OF POLIOMYELITIS.

DURING the past week the epidemics of poliomyelitis have continued to increase in Massachusetts and to decline elsewhere throughout the country. In New York City on October 6, the number of cases reached a total of 9118, with 2321 deaths. In New York State, outside New York City, the total number of cases on September 26, was 3301, with 589 deaths, and in New Jersey on the same date, 3571. On September 18 the number of cases in Pennsylvania reached a total of 1308; in Minnesota, 669; in Connecticut, 789, and in Illinois, 563.

In Massachusetts 198 new cases of poliomyelitis were reported during the first seven days of October, making a total of 1215 in this State since January 1. During 1915 there were only 135 cases reported. There were 151 in 1914, 361 in 1913, 169 in 1912, 232 in 1911, 845 in 1910 and 923 in 1909. Of the total number of cases in the present epidemic, 245 have been in Boston. In this epidemic thus far there have been 150 deaths, of which 16 occurred in July, 39 in August, and 95 in September. There have been 284 cases in Boston and 82 in Holyoke.

In last week's issue of the JOURNAL we noted editorially the organization of the Harvard Infantile Paralysis Commission to conduct research into the transmission and treatment of poliomyelitis, and to constitute a clearing-house for the collection and free distribution of therapeutic blood serum. At the close of the first week of its activity, this commission issued the following report of its work:

"The commission has assisted in the diagnosis and treatment of 20 cases. The serum obtained from the blood of those who have recovered from the disease in the past has been given in 14 cases. Of these, two, who had been ill for some time, died; four were paralyzed before the serum was given, and of the remaining eight, who were given serum in the earliest stages of the disease, none has as yet developed paralysis. These results are encouraging for the use of serum in the earliest stages of the disease.

"Too much emphasis cannot be laid upon the fact that beneficial results from the use of serum can be hoped for only when it is given in the very earliest stages of the disease, and before the evidence of even the slightest paralysis appears. The experts of the commission are on call day and night at the Harvard Medical School to respond to requests from physicians for assistance in the early diagnosis of the disease and for administering serum, if desired. The serum and the services of the diagnosticians are furnished free of charge by the Harvard Commission.

"More serum is urgently needed if the commission is to respond to all the demands made upon it. In the first week 15 persons have volunteered and permitted the required small amount of blood to be taken from them by a process which is without the slightest danger. The commission will gladly pay the traveling expenses of those who wish to volunteer and will come to the Harvard Medical School."

On October 3, Dr. Linsley R. Williams, of Albany, New York, deputy state commissioner of health, announced that the New York State Department of Health had organized a comprehensive plan of after-care for survivors of poliomyelitis throughout the state. Outside of New York City these number 2712. To establish and administer the details of this work, Dr. Robert W. Lovett, professor of orthopedic surgery at the Harvard Medical School, has been appointed. In addition, he will conduct clinics at various places in every county of the state, and will disseminate instruction relative to re-education of paralytics. Dr. Armitage Whitman of New York City, and Dr. John P. Hodgins, of Boston, will be associated with Dr. Lovett, and will devote their entire time to the work.

### COLUMBUS AND SYPHILIS.

A PARTICULAR pertinence attaches to the publication, as the leading article of the present issue of the JOURNAL, on Columbus Day, of Dr. Downing's scholarly paper on the question of the American origin of syphilis and its impor-

tation into Europe by the returning sailors of Columbus. Whatever the ultimate decision on this point, his article directs attention to an interesting and important topic of medical epidemiologic history, and to the classic contribution of Fraeacstor, which should be familiar to physicians as the beginning of the literature of this disease.

### MEDICAL NOTES.

AMERICAN HOSPITAL ASSOCIATION.—The eighteenth annual meeting of the American Hospital Association was held at Philadelphia, on September 26 and 27, under the presidency of Dr. Winfield H. Smith, superintendent of the Johns Hopkins Hospital, Baltimore. In his presidential address at the opening session, Dr. Smith discussed the subject of political domination of the administration and staff appointments of municipal hospitals.

MENTAL DEFECTIVES IN THE DISTRICT OF COLUMBIA.—The Children's Bureau of the United States Department of Labor has recently investigated the subject of feeble-mindedness in the District of Columbia. Of the 33,000 inhabitants of the district, there are about 1500 insane, and in addition, 798 feeble-minded. Of these feeble-minded, 97 were in appropriate institutions, 249 in inappropriate institutions, and 452 were not in institutions.

YELLOW FEVER IN SOUTH AMERICA. Report from New York states that, on September 26, Dr. William C. Gorgas and four other members of the Rockefeller Yellow Fever Commission, of which he is chairman, returned to the United States aboard the steamer *Bravo* from Porto Rico after a tour of inspection through Ecuador, Peru and Colombia. The commission reports that yellow fever was found in only one of the ports visited, namely, Guayaquil, Ecuador, where the disease has been endemic for the past fifty years, and the deaths from it average 35 a month. On October 7 the commission again sailed from New York for Rio Janeiro, Manaus, Pernambuco and Bahia.

PIERAGE FOR A CANADIAN PHYSICIAN. It was announced in the *London Gazette*, under date September 8, 1916, that Dr. Gervase Percy Alexander, Esq., had been appointed to the House of Lords under the title of Baron of Colham. This action represents the award of the ancient barony of Colham to a Canadian physician. This barony, of which there should not be confusion with the barony of Colham, was suspended in 1603. Alexander, Dr. Gervase Percy Alexander, Esq., has recently died, and the title has been passed on to a new peer.

"As long ago as 1912 the proceedings took place before the committee of privileges, which resulted in the calling out of abeyance of the Baronies of Strabolgi, Burgh and Dudley, and the restoration of the Barony of Cobham. It was in 1487, 1322 and 1313 that the three former peerages were created by writs of summons, and they became united in the person of a Lord Burgh, who died in 1597, leaving four daughters, his eventual coheirresses, amongst whom the titles fell in abeyance. The petitioners claimed to be the representatives of one of the daughters. The last holder of the three baronies was the Lord Cobham who was attainted of high treason in 1603, and died before 1606. He was the tenth baron, and before the committee of privilege it was shown that Henry de Cobham was summoned by writ as a peer in 1313."

**CHANGES IN COST OF DRUGS.**—Report from New York on September 29 notes the following recent changes in the cost of drugs.

"Sharp advances occurred in denatured and wood alcohol, owing to an increase in domestic and export trade. Sales of muriate of potash were reported at a further material rise.

No new features developed in the opium situation. There was seemingly no improvement in the demand from domestic buyers, but the market remained steady at the late advance to \$11 per pound for gum. Powdered and granular were unchanged at \$11.70 and \$11.85 per pound, respectively.

Denatured alcohol was higher. Demand for domestic and export account has increased recently, and leading distillers announced an advance in prices of five cents per gallon to 55 and 57 cents, according to quantity, the inside figure being for carloads.

Wood alcohol was also advanced five cents per gallon by leading distillers to 70 cents per gallon for 95 per cent., and 75 cents for 97 per cent in carloads.

Glycerine was advanced by leading Eastern refiners to 44 cents per pound for chemically pure in drums."

**DECLINE OF THE ENGLISH BIRTH RATE.**—The British National Council of Public Morals appointed in 1913 a commission to investigate the causes of the declining British birth rate, and to make recommendations upon means for combating them. This commission has recently issued its report. After reviewing the evidence of vital statistics and testimony, the commission postulates the following propositions which it considers to be definitely established.

"1. That the birth rate has declined to the extent of approximately one-third within the last thirty-five years.

2. That this decline is not, to any important extent, due to alterations in the marriage rate, to a rise of the mean age at marriage, or to other causes diminishing the proportion of married women of fertile age in the population.

3. That this decline, although general, has not been uniformly distributed over all sections of the community.

4. That on the whole, the decline has been more marked in the more prosperous classes.

5. That the greater incidence of infant mortality upon the less prosperous classes does not reduce their effective fertility to the level of that of the wealthier classes.

On the economic and social aspects of the subject the commission drew attention to the argument that an improvement in the birth rate would be facilitated by such conditions as greater security and regularity of income, with adequate insurance against unemployment among all ranks of workers. This view, they point out, is not supported by the statistical evidence available. Not only do the better-to-do classes restrict more closely the size of their families, but even among certain of the wage-earning classes the birth rate varies inversely with the income.

In a section of the report dealing with the housing question, the commission put on record their opinion that both in town and country the present state of things makes the rearing of large families by the working classes a matter of great difficulty and has an effect upon the birth rate. Other sections deal with the medical aspects and the moral and religious aspects of the subject.

An addition to the report is signed by twenty-four members, who are of opinion that something more will be expected from the commission. They deal with two questions:

(1) Is the present decline of our national birth rate regrettable?

(2) If it is regrettable, is it preventable, and if so, how?

The signatories set out reasons why they consider an increase of the population desirable, so far as it is consistent with improvement. They point out that with more intensive culture of the land this country could satisfactorily support a larger population, and that this possibility is much extended if we take into account the whole British Empire. A number of proposals, many of them of an economic character, are also put forward for consideration as tending to further the object in view. They include a living wage, bonuses for families under certain conditions, relaxation of the income-tax arrangements, increased facilities for good education, adequate housing accommodation at reasonable rents, and measures to encourage the full development of natural resources both at home and in the Dominions beyond the seas."

#### EUROPEAN WAR NOTES.

**AMERICAN MOTOR AMBULANCES IN RUSSIA.**—Report from Petrograd states that, on September 25, a fleet of fifteen motor field ambulances, presented by a group of Americans to the Russian government, was formally accepted by the

Empress Alexandria and the Grand Duchess Tatiana. The presentation was made by Captain Philip Lydig and Dr. Philip Newton, under whose command the cars were sent to the front on September 26.

**WAR RELIEF FUNDS.**—On Oct. 7 the totals of the principal New England relief funds for the European War reached the following amounts:

Secours National Fund .....	\$214,669.17
French Wounded Fund .....	124,277.70
French Orphanage Fund .....	65,431.85
British Imperial Fund .....	65,277.00
Surgical Dressings Fund .....	48,020.45

#### MEXICAN NOTES.

**RETURN OF FIELD AMBULANCES.**—On September 25 the First Massachusetts Field Ambulance, and on September 26, the First Rhode Island Ambulance Company, returned from the Mexican frontier to their respective homes.

**SICK AND DEATH RATES AT THE FRONT.**—Report from Washington, D. C., on September 26, states that during the week ended September 23 the morbidity rate among troops of the National Guard at the Mexican frontier was 2.38, with six deaths, as against 2.13 and five deaths for the week ended September 16. The corresponding figures among regular troops were 2.53 with seven deaths, and 2.63 with two deaths.

#### BOSTON AND NEW ENGLAND.

**THE WEEK'S DEATH RATE IN BOSTON.**—During the week ending Oct. 7, 1916, the number of deaths reported was 209, against 216 for the same period last year; with a rate of 14.33, against 15.05 last year. The number of deaths under 1 year of age was 34, against 48 last year; and there were 62 deaths aged over sixty years, against 57 last year.

The number of cases of principal reportable diseases were: diphtheria, 33; scarlet fever, 9; measles, 3; whooping cough, 6; typhoid fever, 10; tuberculosis, 56.

Included in the above were the following cases of non-residents: diphtheria, 7; tuberculosis, 4; scarlet fever, 3.

Total deaths from these diseases were: diphtheria, 2; whooping cough, 1; typhoid fever, 3; tuberculosis, 11.

Included in the above were the following deaths of non-residents: typhoid fever, 1; tuberculosis, 1.

**NEW ENGLAND ASSOCIATION OF JEFFERSON MEDICAL ALUMNI.**—The tenth annual meeting of the New England Association of the Jefferson Medical College Graduates was held at Hartford, Conn., Tuesday, September 19, 1900 being present. The banquet was held at the Country Club at Farmington, at 8 p.m., transportation being provided by auto from Hartford by Dr. Eckley R. Storrs, vice-president. The opening address was made by Vice-President Storrs, and the reports of the secretary

and treasurer were read and accepted, and the following officers elected for 1917: president, Eckley R. Storrs, Hartford, Conn.; vice-president, Albert C. Getchell, Worcester, Mass.; treasurer, Frank I. Payne, Westley, R. I.; secretary, Wallace P. MacCallum, Boston, Mass. The party then adjourned to the banquet hall, where Dr. J. W. Felt, of Hartford, acting as toastmaster, introduced the following speakers, with these subjects: Address of Welcome, Hon. F. A. Hagarty, Mayor of Hartford; "Jefferson and Its Relation to Amalgamation," Prof. Edward Parker Davis, Jefferson Medical College, Philadelphia; "Foilables in Medicine, from an Insurance Standpoint," W. G. Cowles, Esq., Travellers' Insurance Company, Hartford; "Hartford's New Water System," Caleb M. Saville, C. E., Hartford; "Things That I Have Heard about Doctors," William H. Worrell, Ph.D., Professor of Arabic, Hartford Theological Seminary. After brief talks by Dr. George L. Porter, 1865, of Bridgeport; John T. Farrell, M.D., of Providence, R. I.; James A. Mansfield, M.D., of Boston; and Charles A. Riley of Boston, the party adjourned. It was voted to hold the next annual meeting at Worcester, Mass.

**INSANITY IN MASSACHUSETTS.**—According to the recently issued seventeenth annual report of the State Board of Insanity, covering the year ended November 30, 1915, there were 18,137 people under its care, being 1 such person to every 203 of the population of the State. Of this number, 14,746, or 81%, were insane; 2604, or 14%, feeble-minded; and 619, or 3%, epileptic (same). Their increase for the year was 833. The whole number of such persons under public care was 17,702, under private care, 435. The increase of such persons under public care for the year was 844, their average annual increase for the last five years, 596. The nativity of first cases of insanity does not differ materially from the percentages of the previous year. Exclusive of 37, or 1.17%, whose birth-places were unknown, 1241, or 39.90%, were born in Massachusetts; 1522, or 18.93%, in New England; 1692, or 54.41%, in the United States; and 1418, or 45.59%, in foreign countries.

**TYPHOID FEVER IN BOSTON.**—A recently published monthly bulletin of the Boston Health Department shows that during the first eight months of 1916 only twelve deaths from typhoid fever occurred in this city, the lowest number on record for that period since 1896. In 1915 Boston had the lowest typhoid mortality of any large American city, only one death occurring. "This rate will place Boston at the head of the large European cities, which have averages 1, London, Berlin, 1.5; Vienna, 2.1; Hamburg, Christiania, 2.5; Stockholm, 3.0; and Copenhagen, 3.5."

"We have but to look at the figures of the

to realize the great decrease that has taken place in deaths from typhoid fever in this city. In 1908 there were 158 deaths from this disease, in 1914 there were 66, in 1915 only 40, and thus far this year but 12. During the period between 1906-10 the death rate from typhoid fever was 16.0, in 1914 it was 9.2, last year 5.3, and this year it is hoped that it will not exceed 2.5."

**NEW CLINIC AT BOSTON DISPENSARY.**—On October 2 a new combined clinic for the treatment of diseases of the nose, throat and ear was opened at the Boston Dispensary. It was formed by uniting the previous separate departments for diseases of the ear and of the throat. The new department will be under the direction of Dr. Frederic C. Cobb, with whom will be associated Dr. William E. Chenery, Dr. W. S. Boardman, Dr. Edward R. Newton and Dr. Henry J. Inglis.

**WALTHAM TRAINING SCHOOL.**—The annual graduation exercises for the Waltham (Mass.) Training School for Nurses were held in that city on September 29. The principal address was made by Dr. Charles F. Painter, and diplomas were awarded to a class of thirteen pupil candidates.

**HEALTH WORKERS OF NORTHEASTERN MASSACHUSETTS.**—A regular monthly meeting of the Association of Health Workers of the Northeastern District of Massachusetts was held at Everett, Mass., on September 28, under the auspices of the local Board of Health, and was attended by over three hundred members and guests. The chief topic of the meeting was the prevention of tuberculosis among predisposed children.

Dr. Thomas Harrington, deputy commissioner of the State Board of Labor and Industries, spoke on 'School Hygiene.' He advocated open-air schools, or at least an open-air schoolroom for children predisposed to tuberculosis. He urged that school hygiene should be taught as a necessary step to a successful fight against tuberculosis.

Dr. Richard M. Smith of Boston spoke on 'Tuberculosis in Childhood,' and urged early diagnosis of suspected cases. Dr. John A. Brewin of the Everett Board of Health talked on the problems of the local campaign.

An illustrated health talk was given by Dr. Lyman Asa Jones, director of the division of hygiene of the State Department of Health. 'The Tuberculosis Dispensary System' was the subject of Dr. Eugene R. Kelley, and Dr. Arthur A. Brown, State district health officer, spoke on the problems of the Northeastern district.

The next meeting of the Association is to be held at Newburyport, Mass., on November 9.

**THE FAULKNER HOSPITAL, JAMAICA PLAIN, MASS.**—The twelfth annual report of the Faulkner Hospital, which covers the year ended May

1, 1916, announces a legacy of \$8,000 from the estate of Frances G. Curtis. This is to be held as a fund for maintaining a free bed, the second memorial bed thus far given to the hospital. The nucleus of a fund for another free bed has been started by friends of the hospital in West Roxbury. The most notable feature in the work of the hospital is stated as being the growing demand for maternity service. The building of a maternity ward was seriously considered a year ago, and this year the trustees have voted to erect such a building, and the necessary appropriations have been made. Some of the rooms in the new building intended for patients will, however, have to be used for nurses until funds can be secured to provide additional accommodations for them. Seven nurses were graduated from the training school during the year. It is hoped that it will be possible at an early date to provide a social worker for the hospital in order that intelligent treatment and care can be continued to many patients who are in need of such attention after they leave the hospital.

## Miscellany.

### THE SANITARY PROGRESS AND VITAL STATISTICS OF HAWAII.

In a pamphlet compiled by Frederick L. Hoffman, LL.D., statistician, and issued by the Prudential Insurance Company, is contained a detailed account of the sanitary condition and progress of Hawaii from the time of its discovery by Cook in 1778 to the present day. Physically of a superior type, the native Hawaiians present an interesting study of the effect of civilization and its attendant diseases on a primitive people. Syphilis, according to one authority, was unknown in the islands before the visit of Cook in 1778, but in 1839 the disease was excessively prevalent and malignant. Leprosy is mentioned as having been unknown until about the year 1840, when it is believed to have been introduced by Chinese immigrants. In 1890 the number of lepers segregated at Molokai was 1213, but this number was by no means considered as representative of the full extent of the evil. Smallpox was first introduced in 1853, from San Francisco, and in eight months the disease carried off 8% of the population. The introduction of tuberculosis, and its rapid spread among the native races of the Southern Pacific, according to numerous authorities, dates from the time of the settlement by the Europeans, when the natives were induced to make considerable changes in their mode of life.

As recently as 1872, an official census gave the number of full-blood Hawaiians as 49,044, and only 2487 mixed-bloods of part Hawaiian

many years in preparing herself for this work. In many cases the school attendance has been interrupted before coming to the hospital, and many children here for treatment or other ailment may be defective. Much of the teachers' work is individual along lines of special schools for backward and slow-developing children.

"Children between two and fourteen years of age are admitted to the hospital at any time, no commitment being necessary. All cases are admitted upon the voluntary application of those who are responsible for their care and support. Parents or guardians do not relinquish their rights or responsibility for them further than their care, treatment and training for the time being. Any case may be received without formality if the support of the child has been provided for as to the weekly cost of same. Application blanks and further information may be obtained upon request by addressing the superintendent.

"A certain number of charitable cases are taken, where only part of the expense can be covered by the parent, and a special charity rate of \$3.25 per week has been established for board, care and treatment through the Commonwealth for suitable cases dependent upon the State or city for support.

"The average weekly per capita cost has been \$6. For those outside of Massachusetts the rate is seldom less than cost. If private nurses or any extraordinary attention is required, this charge is graded to fit conditions.

"The income from invested funds now amounts to almost \$340,000, which we hope will be increased to a million dollars before long, as in this way we may be able to care for a greater number of charitable cases, and the contributions of charitable people, the Woman's Board, and others, make it possible to offer rates below cost, as low as \$3.25 per week. In cases unable to pay more, children may often be supported by some society organization of their own community, a written agreement for support being required. As the hospital is supported largely by voluntary contributions, donations of all kinds are earnestly solicited. Funds of smaller or larger denominations are accepted. A free bed can be maintained by an annual payment of \$200. An endowment of \$5000 will maintain a free bed permanently. We now have ten free beds. This applies to patients within the State. For those outside the State, \$10,000 at least will be necessary. Notice of a desire to establish a free bed may be sent to the superintendent of the hospital or to any other officer of the institution.

"All kinds of bed linen, furnishings and hospital equipment and appliances for deformed infantile paralytic children are needed, as well.

"We hope to increase our funds to secure a new operating room and x-ray room, a workshop for making all appliances for the deformed children, a plaster room, also an industrial room

which should be fully equipped, as well as playthings to establish a play pavilion for all the children.

"We hope that the many friends of the hospital may help by the solicitation of others, who can help so much to bring sunshine and happiness to those who have been unfortunate through accident and disease."

## OCCUPATION AND HEALTH IN ADOLESCENCE.

It is so well recognized that certain occupations may involve serious dangers to young, growing persons that most States now have their child labor laws. Massachusetts, which has been a leader in legislation of this character, is now engaged in a systematic effort to collect information that may be of value in determining the need of changes in its present laws and regulations governing the employment of minors. At the request of the Massachusetts Board of Labor and Industries, Assistant Surgeon M. Victor Safford of the United States Public Health Service was detailed by the Federal Government to cooperate with the State authorities in a study of the effect of employment in various occupations on the health and physical development of children now permitted by law to work therein. A report of this study with respect to the cotton manufacturing industry of Massachusetts has just been published by the Federal Government as Public Health Bulletin No. 78, entitled "Influence of Occupation on Health During Adolescence."

The physical condition of over 600 boys between the ages of 14 and 18 employed in this industry in different parts of the State received careful study. It was brought out that in Massachusetts, boys between these ages, for the most part, do not remain long in the cotton mills. This fact and the strict regulations of the State governing the employment of minors may not make some of the conclusions reached in this local investigation equally true elsewhere, but among the facts disclosed, the following may be mentioned:

A considerable proportion of the younger boys, and also of those over sixteen, were undersized and physically undeveloped for their ages, while those between fifteen and sixteen averaged larger than other classes of boys of their age with which comparisons were made. This fact is explained by the accumulation in the mills of strong boys waiting to reach the age of sixteen to go into permanent "full time" occupations. The presence of a noteworthy proportion of undersized boys is not ascribed to the effects of the occupation, but to the fact that the cotton mill offers one of the few chances of employment for undersized boys. Evidence of injurious effects of their work or working conditions, even of the temperature and humidity of the mills, on normal boys, was seldom found, although further

investigation of possible effects of atmospheric conditions is recommended. Probably as a result of the State regulations relative to the issuance of employment certificates comparatively few cases of dangerous diseases were discovered. There was, however, a wide variety of defective conditions disclosed by the investigation, many of them of such a character as to impair seriously the future health and economic usefulness of the individuals concerned, if not remedied.

### HEALTH INSURANCE.

TWENTY-FIVE out of every 1,000 employees in American industries, according to recent statistics, are constantly incapacitated by sickness, the average worker losing approximately nine days each year on this account. This "non-effective rate" for the great army of industrial workers in the United States barely suggests the total money loss to employers and employees. The lessened efficiency, the effects of reduced earnings in times of sickness, as well as the cost of medical attention, and the economic loss from deaths, swell the cost to industry and to the Nation to almost incalculable figures.

That much of this loss is nothing less than preventable waste, and that this waste can be largely reduced by a properly conducted system of governmental health insurance for wage-workers, are conclusions set forth in Public Health Bulletin No. 76, containing the results of a study of "Health Insurance—Its Relation to the Public Health," just issued by the United States Public Health Service.

The preventive value of health insurance is given especial emphasis in this study. "Any system of health insurance for the United States or any State should at its inception have prevention of sickness as one of its fundamental purposes," says the bulletin. "This country should profit by the experience of European countries, where prevention is being recognized as the central idea necessary to health insurance if health insurance is to attain its greatest success in improving the health and efficiency of the industrial population."

Such a system, it is pointed out in the bulletin, would:

1. Provide cash benefits and medical service for all wage-earners in times of sickness at much less cost than is now possible. Adequate medical relief would thus be placed within the reach of even the lowest paid workers, who are most subject to ill-health.

2. Distribute the cost among employers, employees, and the public, as the groups responsible for disease-causing conditions, and afford these groups a definite financial incentive for removing these conditions. This can be done by means of small weekly payments from employees, supplemented by proportionate contributions from employers and government at a

rate reducible in proportion to the reduction of sickness.

3. Become an effective health measure by linking the cooperative efforts of the three responsible groups with the work of National, State and local health agencies, and by utilizing these agencies in the administration of the health insurance system.

4. Afford a better basis for the cooperation of the medical profession with public health agencies.

5. Eliminate the elements of paternalism and charity-giving by making employees and the public, as well as employers, joint agents in the control of this fund.

"A governmental system of health insurance," concludes the study, "can be adapted to American conditions, and when adapted will prove to be a health measure of extraordinary value."

### AN INSTANCE OF MEDICAL HEROISM.

At the closing exercises of the fourteenth session of the United States Naval Medical School, at Washington, D. C., on April 12, 1916, the commencement address, on "The Humanity of Surgery," was delivered by Dr. Hubert A. Royster, of Raleigh, N. C. It contained an account of heroism on the part of the doctor deserving of note in the annals of his profession.

"Surgeons everywhere have been called upon to perform services of the most heroic kind, and, he it said to their credit, they have been found, for the most part, sufficient for their tasks. Even in civil life examples are not lacking. My own state presents an instance of the highest type in the person of Edmund Strudwick, who by one deed would have the title of hero. Not in all the annals of history have I read of nor is it in my mind to conceive of firmer devotion to duty or of more daring fortitude than he exhibited. When near sixty years of age, he was called to a distant county to perform an operation. Leaving on a 9 o'clock evening train, he arrived at his station about midnight, and was met by the physician who summoned him. Together they got into a carriage and set out for the patient's home six miles in the country. The night was dark and the road was rough; the horse became frightened at some object, ran wild, upset the carriage and threw the occupants out, striding off. The country doctor, who had been forwarded word by mail of the accident, was called to the scene and found Dr. Strudwick's leg just above the ankle. As soon as he had sufficient strength to get up, he called aloud for help, and the physician, who had crawled to the spot, found him lying on the ground, his leg crushed. The physician, who had been summoned to the house, where he found the patient, and the

of himself or of his companion; but, coming out of his stupor, he faintly remembered the occurrence and at once dispatched a messenger to the scene of the accident. Dr. Strudwick was still leaning against the tree, calling now and then in the hope of making some one hear, when the carriage came up about sunrise. He got in, drove to the house, without allowing his own leg to be dressed, and, sitting on the bed, operated upon the patient for strangulated hernia with a successful result. 'Greater love hath no man than this.' "

The daily heroism of the physician in encountering the incidental risks of his profession is frequently exaggerated; but such conduct as that of the above incident demands a degree of physical fortitude seldom observed except under conditions of war.

### Correspondence.

#### A REJOINDER ON WORKMEN'S COMPENSATION.

*Mr. Editor:* I wish to make some criticisms of statements in an article in your last issue above the signatures of M. A. Tighe, M.D., and J. A. Mehan, M.D.

When these gentlemen say: "We believe that any act which deprives John Smith, a human being, of his divine right to select his attendant, when either accident or sickness befalls him, is grossly unfair,—no matter who pays the bill,"—I cannot believe they mean or believe what they say. The law specifically states that he shall select only attendants of certain qualifications and holding certain licenses, and if John Smith, paying his own bills, an honest believer in Christian Science or Osteopathy, should select one from these cults as an attendant on one of his family ill with diphtheria or typhoid fever, he would find himself and his attendant in trouble with the law. And the law that would abridge his liberty is an offspring and creation of our medical organization.

These gentlemen also state, "The service offered by the Insurance Associations is positively no better than the workman himself could and would select." This may or may not be true. It cannot be proven or disproven, and it would be idle and unprofitable to discuss it. When the Workmen's Compensation Act compels the employer to care for the workman injured in his employ, it seems but common justice that the employer himself, or through the Insurance Company paying the bills, should have the right, at least, to insist that the injured should be treated only by competent, experienced surgeons, and I think that if these gentlemen were employers, instead of physicians, they would see it in that light. There is no sentiment with Capital; and the employer or the Insurance Company do not select a surgeon because of race, creed, affability or friendship. With them it is a matter of cash results. Their only interest is to see that the injured workman recovers as soon as possible, with the least possible permanent disability, and when, as has recently occurred, a workman with a comparatively trivial injury dies after a long and painful illness from seeming neglect, incompetency, or inexperience on the part of his attendant, the company, in justice to themselves and to their injured workman, should have the right to debar this surgeon from further service in their employ.

A patient in a hospital generally accepts the service of the medical and surgical staff in that hospital without a sense of hardship. If, for personal or

other reasons, he prefers someone outside of that staff, he is at liberty to avail himself of that other service, providing he is willing to pay for it. Where are the cases dissimilar?

A too zealous insistence on regulating the relations between the medical profession and society at large has often brought our profession into disrepute from the days of Molière down to the present time.

WILLIAM G. REED, M.D.,  
September 29, 1916. Southbridge, Mass.

#### APPOINTMENTS.

BOSTON CITY HOSPITAL.—DR. JOHN G. BRESLIN has been appointed assistant resident surgeon of the Haymarket Square Relief Station, and DR. BERNARD F. DEVINE resident surgeon of the East Boston Relief Station.

BOSTON DISPENSARY.—DR. MAYNARD LADD has been appointed physician-in-chief of the Children's Department of the Boston Dispensary.

TUFTS MEDICAL SCHOOL.—DR. ANDREW H. RYAN has been appointed professor of physiology, DR. CHARLES H. BAILY associate professor of histology, and DR. ARTHUR L. CHUTE associate professor of surgery.

UNITED STATES CENSUS BUREAU.—DR. WILLIAM H. DAVIS, for some years vital statistician of the Boston Health Department, has been appointed chief statistician of the division of vital statistics of the United States Census Bureau.

#### SOCIETY NOTICE.

WORCESTER DISTRICT MEDICAL SOCIETY.—The regular meeting will be held in G. A. R. Hall, 55 Pearl Street, Worcester, at 4.15 P.M., Wednesday, October 11, 1916.

#### PROGRAM

I. Obstetrical Preparedness, by Dr. Charles M. Green, of Boston.

II. Report of Committee to the "First Legislative Convention of Massachusetts Physicians." All members interested in the Workmen's Compensation Act should be present to discuss and act on the report. Attorney Frank F. Dresser will tell us something of the legal aspects of the situation and what we may reasonably strive for.

Remember that the censors meet for examinations of candidates on the second Thursday in November. Prospective members should get in touch with the secretary before that day.

ERNEST L. HUNT, *Secretary*.

#### NOTICES.

MASSACHUSETTS GENERAL HOSPITAL, ETHER DAY EXERCISES.—Members of the medical profession are invited to attend the Ether Day exercises in the Moseley Memorial Building of the Massachusetts General Hospital (entrance on Fruit and North Grove Streets), at 4 P.M., on October 16, 1916.

The address will be given by Dr. Haven Emerson, Commissioner of Health, New York City. Subject:—Preparedness for Health.

CARTWRIGHT LECTURES.—The Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons will be delivered at the College of Physicians and Surgeons, 437 West 59th Street, New York, Tuesday and Wednesday afternoons, October 24 and 25, 1916, at five o'clock, by Richard M. Pearce, M.D., Professor of Research Medicine, John Herr Musser Department of Research Medicine, University of Pennsylvania, Philadelphia. Subject:—The Spleen in its Relation to Blood Destruction and Regeneration. The public is cordially invited to be present.

HARVEY SOCIETY LECTURE.—The first lecture of the course for 1916 of the Harvey Society will be given on October 14, at the New York Academy of Medicine, New York City, by Professor J. S. Haldane, University of Oxford, on "The New Physiology."

## SYMPOSIUM ON GOITRE.

## I.

## SURGERY OF THE THYROID GLAND.

By C. A. PORTER, M.D., Boston.

THE surgical lesions of the thyroid which we have to consider are infections; simple bilateral diffuse hyperplasia, or hypertrophy of the gland; fetal adenomata; cysts; adenomata, and irregular colloid tumors, often in combination; malignant tumors, sarcomata and carcinomata; and finally, toxic goitres and true exophthalmic goitre or Graves' disease. In infections, we have to do with drainage operations; at times, removal of portions of the gland; in the condition of adenomata, cysts, and colloid goitre, removal of the cyst, enucleation of the tumor or, as in the case of colloid growths, a sufficient removal to relieve obstruction to the trachea, esophagus, etc., or for cosmetic purposes; next, removal of tumors which, owing to their appearance late in life, or rapid growth, suggest the possibility of incipient malignant disease, finally attempt at cure or palliation, *i. e.*, tracheotomy, of actual malignant disease.

Of the goitres with toxic symptoms, so called hyperthyroidism, there are two types; those in which a goitre has been present for varying lengths of time, followed ultimately by toxic symptoms, with or without exophthalmos; and perhaps the *true type* of primary Graves' dis-

ease, in which general toxic symptoms not rarely precede or quickly follow the development of an enlarged thyroid.

1. In many infections there is undoubtedly a process in the thyroid gland which is shown by swelling, tenderness, increased size, fever, leucocytosis, pain—often referred to the back of the ear or neck—difficulty in breathing or swallowing. As a rule, under such conditions the infection spontaneously subsides without the formation of pus. Occasionally a definitely suppurative thyroiditis takes place with pus formation, requiring evacuation on ordinary surgical principles. I have seen a few cases which were diagnosed as ordinary deep cervical abscesses. It is not the large venous supply of the gland, pyogenic infection, and the results of proper drainage which prevent suppuration. However, as a rule, the acquired toxæmia, which develops from destruction of the thyroid glands, which is caused by scar tissue. Tumors of the thyroid gland in syphilis very rarely, if at all, occur in the thyroid gland.

poles are left of symmetrical size in order that one side of the neck may not be smaller than the other.

3. Fetal adenomata occur as single or multiple, nodular, circumscribed tumors in one or both lobes, developing early in life, or at any period. They lead often to marked deformity, to pressure on the trachea or esophagus,—depending upon their location. If the thyroid enlargement takes place forward, between the sternomastoid muscles, pressure signs are often absent. If, however, a relatively small tumor grows behind the insertion of the sternomastoid muscle, pressure symptoms are apt to arise as the muscle holds back the tumor from any outward growth. With these fetal adenomata there occur varying degrees of toxic symptoms on the part of the heart, nervous system, etc., which are rarely, however, accompanied by exophthalmos.

Goetsch believes that these adenomata have the power of secreting an excess of thyroid juice, which explains the marked relief of general toxic symptoms which almost always follow their removal. Operation, though at times difficult, is most satisfactory, and consists either of enucleation of the nodules from the thyroid tissue, or occasionally it is simpler to do a lobectomy, provided enough thyroid may be left behind in the other lobe to carry on the function of the gland.

Cysts are not uncommon, varying in size from a marble to enormous tumors containing a couple of quarts. Into them, now and then, occur sudden hemorrhages, which may cause even alarming pressure symptoms, but apart from this, their harmful effect is purely mechanical. If a cyst is suspected no harm will come from aspiration with a hypodermic needle, for diagnostic purposes, followed, if deemed advisable, by the injection of carbolic acid, corrosive sublimate, or some irritant designed to prevent recurrence. It is important to make this diagnosis, for treatments by iodine, x-ray, thyroid extract, etc., are absolutely contraindicated and useless in cyst formation. If cysts are increasing in size, or causing obstruction, they should be removed with the technic which will be described in thyroid operations.

5. Colloid is the most common form of thyroid enlargement and varies in all degrees. As a rule, operation is desired for cosmetic purposes, or owing to the formation of large bilateral tumors in the neck, with a varying amount of pressure symptoms. It is surprising to see to what a huge size some of these tumors may develop without causing any symptoms whatever. In other cases thyroid enlargements take place posteriorly, encircling the trachea, or trachea and esophagus, and bring about severe obstructive symptoms. Iodine and thyroid extract, with or without x-ray, sometimes cause diminution of these tumors, but in general their effect is slight, and surgery fulfills here one of its safest indications. In such thyroid enlargements, occurring before puberty, operation

should be delayed as long as possible, lest too much of the more or less active gland be removed and interfere with the proper development of the individual.

In regard to the technic of operations for benign tumors of the thyroid, the first question for consideration is the choice of the anesthetic. As my experience increases, I am more and more in favor of local anesthesia, where the mental attitude of the patient is satisfactory. While a change from local to general anesthesia is always possible, it is time-consuming, increases danger of infection if the patient struggles; and much judgment should be used in endeavoring to select those patients who will satisfactorily put up with the idea of being conscious while their neck is operated upon, or occasionally bear a little pain or sense of dragging. I give sulphonal—grains 20 to 30—the afternoon previous to operation, and one or two doses of morphia, commencing an hour and a half before the appointed time. With the second dose, 1/120 of a grain of scopolamine, which may be repeated just before operation, if the patient is not sufficiently drowsy. This combination of sulphonal, morphia and scopolamine is most satisfactory when it works well, but occasionally there is excitement instead of quiet, a condition like coma vigil,—the patient sleeping until the surgeon starts to do something, then waking up and resisting. If a general anesthetic is to be administered in such instances, it must be given with great care, as the patient is often overdressed for a satisfactory ether operation. A pillow should be placed between the shoulders, so that the neck may be hyperextended, the table in moderate Fowler's position, facing a good light. No pains should be spared for a proper posing of the patient before operation, as great difficulty will be found in carrying out a proper technic if the neck slumps backward. There is no doubt that the collar incision of Koehler is the best for these operations. This may be placed across the bottom of the neck, where a necklace will later conceal the scar, or it may be made by a low incision over the sternum, when no scar will be visible unless a low-neck is worn. I use a 1 or 2% novocaine solution with 1-40,000 adrenalin chloride. It is best to mark out the line of incision by an intradermal injection of the solution, which should bring out a white wheal on the skin. The novocaine acts thus quite quickly from tension, more slowly from its anesthetic action. If you will recall your anatomy you will remember that all the nerves supplying the front and side of the lower neck emerge from the posterior border of the sternomastoid muscle, from its mid point downwards for an inch and a half; the superficial cervical branch, the inner, middle and outer branches of the supraclavicular nerves. While we are waiting for the novocaine in our line of incision to act, these nerves at this point should be anesthetized by deep massive infiltra-

tion. The skin and platysma muscle should next be incised, usually from external jugular to external jugular, the posterior incision extending somewhat upward, rather than transversely, in the lines of cleavage of the skin. The upper flap should be dissected to the level of the bottom of the thyroid cartilage, the lower down to the sternum. The enlarged anterior jugular veins next come into view, and must be carefully clamped and tied between ligatures. The sternomastoid muscles are then to be dissected free and retracted. If the tumor is a large one, there is no objection to dividing these muscles a half to two-thirds through; mattress sutures will ensure no deformity. The surgeon has next to consider the advisability of separation of the sterno-hyoid and thyroid muscles in the median line, with lateral retraction, or a transverse division of them at a higher level than the skin incision. There is little doubt that separation is preferable to division on account of less post-operative pain in swallowing, and freer movements when the wound is healed. Large or vascular tumors require free exposure for neat and bloodless work, and the muscles must then be divided. No time will be lost, and convenience assured, by immediate ligation of all skin vessels. Fine plain catgut should be used rather than silk, as in many instances chronic gut or silk ligatures are discharged from just under the skin some time after the wound has apparently healed. The intrinsic capsule of the thyroid varies much in thickness and in adherence to the gland. Any previous infection or treatment with boiling water, or x-ray, makes its removal more difficult. Anteriorly the capsule is of no importance, but if we are to operate upon both sides of the gland, it marks behind the curtain beyond which lie the recurrent nerves and the parathyroid bodies. When the muscles have been well retracted, careful inspection of both lobes is necessary to determine what operation shall be done,—enucleation of a cyst or an adenoma, removal of the anterior two-thirds or three-fourths of both lobes, or hemithyroidectomy on one side, and upper partial lobectomy on the other.

Lobectomy is comparatively simple and bloodless. The gland is grasped with gauze or a double hook, pulled toward the median line, and the upper and lower vessels clamped between forceps and divided. In spite of care there is often some troublesome bleeding near the middle of the gland, where the inferior thyroid breaks up into a number of branches. An injury to the nerve usually occurs from hurried grasping of a bleeding vessel through the capsule. Local anesthesia has the great advantage that it forces the surgeon to work gently and slowly, and any change of voice can be immediately noted. As a rule, these manipulations are painless, but occasionally the patient complains when a ligature is tied, or the tumor is dragged upon. Several times I have enucleated a cyst or tumor from

behind the sternum, and have been surprised at the freedom from pain. If supplementary injections of novocaine are necessary, it must be remembered that several minutes are required for complete anesthesia. The common error made is to begin without this delay. In large, irregular tumors, Balfour's suggestion is valuable, *i.e.*, the division of the isthmus, and separation from the trachea of the two halves of the glands from within outward. After the amount to be removed has been determined, every effort should be made to control the blood supply by deep mattress sutures or pressure by the finger on the vessels at the base of the lobe. When all bleeding has been stopped, the remains of the lobe are then sutured, leaving behind the lower rather than the upper poles. In all cases of tracheal obstruction, local anesthesia is invaluable. When once the trachea has been bared and is clearly visible to the eye, a general anesthetic may be safely administered, if necessary. In spite of all precautions, hemorrhage (sometimes serious) takes place in a definite proportion of cases. Most frequently a vein is torn in delivering the gland,—a danger much increased when patients are cyanotic from obstruction or vomiting under ether. In general, drainage can be omitted. If used, a small stab wound through the lower flap is preferable to its insertion through the line of incision. Whenever there is mild infection of a drain through the incision, there is apt to occur a dimple adherent to the deeper tissues, which causes an unsightly deformity, and dragging on deglutition. The platysma must always be sutured with care; the skin incision closed either by a sub-cuticular catgut suture, or interrupted fine silk or horsehair stitch loosely tied and removed within three days. With this technique the scar of the collar incision is practically invisible. A moist dressing for twenty-four hours allows oozing from the drain or between the stitches. At the end of two days the drain should be removed, and in the mean time great care must be taken to prevent infection from looseness of the dressings. I use a single large gauze sponge snugly held to the skin by adhesive plaster at the top. This is raised like a lid, and the dressing applied, which is held in place by a row of pins behind the neck, crossed and pinned to the front. For severe cases, the dressing is made of painful, and patients are often annoyed by means and methods which are not necessary. Drainage is seldom necessary, and if used, there is usually no need of a drain tube, the serum which collects being removed by frequent aspiration. For the scar of the collar incision, it is better to be prepared with a small piece of fine mesh silk, which is sutured to the ends of the incision, and the ends of the platysma are sutured to the ends of the incision, and the tumor is dragged upon. Several times I have enucleated a cyst or tumor from

ondary hemorrhage. Three times a recurrent laryngeal nerve has been injured, either in the dissection, or carelessly grasped in the attempt rapidly to control bleeding. Though some of the tumors and cysts have been very large—one filling up a third of the superior mediastinum, and another adherent to the sternum beyond its middle—I have had no death in more than 100 cases until last month, when an old lady of 65, who for 40 years had had a very large cystic tumor, died from hemorrhagic nephritis and bronchopneumonia.

There have been a few instances of continued growth of the tumor or formation of a new cyst, making necessary a second, and twice a third operation. The surgery of non-toxic goitre, then, though often difficult, is extremely satisfactory—the cosmetic results good. The exact opposite is true of malignant disease. In the last fifteen years there have been twenty operations at the Massachusetts General Hospital. Of these, 17 were cancer and 3 sarcoma. One case was 25 years old, one 29, one 32, one 33 all the others over 40. The oldest patient (63 years of age) had had an enlarged thyroid for twenty years, with rapid growth in the last two. There were five cases of very long duration of a goitre subsequently undergoing malignant degeneration,—one 35, one 25, one 20, one 12, one 7, another 4 years after onset. This shows quite clearly what my experience confirms,—that the development of an enlarged thyroid after fifty, or rapid increase in a long-standing goitre, is an indication for immediate operation. When once the diagnosis of cancer is clear, from the stony hardness of the tumor, paralysis of the recurrent laryngeal nerve, and enlargement of the adjacent lymphatics, a radical operation is practically hopeless. The only chance of cure rests in a thorough operation before the carcinoma has spread beyond the capsule of the gland. In one private case such an operation was done, with the removal of a portion of the esophagus. For a year there was complete comfort, but recurrence then took place. In two other patients over sixty, with rapid growth in a few months, recurrence followed operation too soon to make it worth while. Where obstruction to respiration makes tracheotomy necessary, local anesthesia is clearly indicated. This will be found to be a most bloody and trying operation, not rarely followed by secondary hemorrhages; pneumonia and bleeding commonly end the life of these wretched patients.

We have next to consider the toxic cases—so-called hyperthyroidism. As my paper deals only with the surgical aspects of Graves' disease, I shall not enter into the various theories as to its causation and complex relations or interrelations with the other glands. One thing remains clear—the etiology is not yet thoroughly understood. It is also, I think, impracticable to divide the toxic cases too minutely into groups. Broadly speaking, however, there are two

types: one, where the patient for months or years has had an enlarged thyroid, and subsequently developed the toxic symptoms; another group where, preceding any manifest thyroid enlargement, there is nervousness, tachycardia, palpitation, etc., or the general symptoms develop with an increasing enlargement of the gland. If any rough distinction can be made, the first class may be called tumors with hyperthyroidism; the second, true cases of exophthalmic goitre. It is in this latter class (2)—though, of course, there are exceptions—that we find the most severe toxemia, exophthalmos, and the greatest loss of weight. What, at present, are the indications for surgery in these two types of cases? What are the dangers of operation, and what has surgery to offer better than medical treatment? Quite recently the x-ray, being safe and favorably regarded, is being used more and more. The invention of the Coolidge tube, which allows measured, massive dosage, may prove a valuable aid in this disease. Personally, I have been in the habit of having one or two thorough treatments previous to operation. I have had little experience with long-continued treatment. While, undoubtedly, marked improvement has occurred, particularly in the milder cases, I have not been impressed with the results, and in one case in particular, I can see very little improvement after a year of treatment. Dr. Seymour, who has recently been following a series of cases, will later give us his impressions. It has one great advantage,—if not persisted in too long,—the element of safety and the absence of scar. There are some surgeons, notably Kocher of Berne, who think that surgery is the ideal treatment for thyrotoxicosis. He operates as early as possible after a very brief period of rest, and refuses operation on all advanced cases. His mortality is small (about 4%), because, in fact, he operates upon a selected group of cases. The general feeling at present is, I think, that all cases of Graves' disease should first be treated by rest and medical treatment. If satisfactory improvement occurs, this may be continued, but is not applicable to wage-earners and those who cannot give up the time. While under neutral bromide of quinine and other drugs, almost miraculous improvement takes place now and then, it is my experience that such cases are apt to recur, and that if lobectomy, single or double partial, has been performed, cures occur more rapidly and are more permanent. I would advise operation of some sort, then, in cases where improvement is unsatisfactory under medical means; in cases which have already lasted more than a year, with commencing myocardial weakness, exophthalmos, etc., or where it is unlikely that medical treatment will act sufficiently quickly to bring about a satisfactory result. Plummer of Rochester believes that after a year, operation is less hazardous than in the early stages. My experience has shown that

Graves' disease in girls from 18-20, particularly if the mental attitude is excitable, has seemed to carry a grave operative prognosis. Another type in which the risk is poor are women between 40 and 50, who are apparently passing through the menopause. The Hebrew race, owing to their neurotic constitution and lack of control, make a calm preparation for operation difficult, and I have had, among them, a comparatively large mortality. There is another group of rather chronic cases of years' duration, with ups and downs,—exophthalmos, rather firm vascular glands, tachycardia, often irregularity of the heart,—in which there is doubt as to whether the patient is actually suffering from Graves' disease or the aftermath of a passed toxemia. It is in this type that the various newer tests are of very great value. I mean estimation of the carbohydrate tolerance, basal metabolism, differential blood counts, injections of adrenalin, etc., in order that we may determine, if possible, whether the symptoms are due to an overactive gland. In these cases it is probable that other glands, the sympathetic system, and the myocardium have been affected; and it is often a nice question of judgment to decide for or against operation.

Before considering operation, there is one thing I wish to emphasize, and that is an increasing conviction that the psychic influences before operation are of extreme importance—in fact, I believe make for recovery or death in certain instances. The surgeon should have absolute control of the situation, and the complete confidence of the patient who, if possible, should look forward to the day of operation, unless we follow Crile in all detail in his "theft of the thyroid." In no other surgical disease do the surroundings, methodical nursing, cheerful mental attitude, etc., count so much; to no other patients do the occasional worries and effects of a large clinic work so great a detriment. If, as I believe, the mental attitude of the patient is so important, it is queer that surgeons have not come to more unanimity upon the choice of an anesthetic. Kocher has always insisted upon local anesthesia, and I have seen him adhere to this rule to, if not beyond, the limit. The Mayos, whose mortality is equally small, have the patient brought to the amphitheater and quietly etherized by the drop method. Crile, as we know, endeavors to carry out his anesthetic conception, planning to keep the actual date of the operation from the patient, and gives gas and oxygen in the patient's bed. As my experience increases, I am more and more in favor of the morphia-scopolamine sequence with local anesthesia, when the patient's mental attitude is favorable and the drugs act well. In a few operations I have had to abandon local anesthesia, owing to the complete lack of control of the patient, and have felt that this abortive attempt was much worse than if I had started with a general anesthetic. Indeed, I will go far

and say that in bad cases of Graves' disease, if anything goes wrong with the preparation for operation, and a patient arrives in a highly excited condition, it is always best to delay for a more favorable opportunity.

From the 185 cases in hospital and private practice which I have had, I have selected the 85 which, at time of operation, showed definite Graves' disease or hyperthyroidism present, or very definite in the immediate past. I have excluded the milder cases of transient hyperthyroidism, and considered them in the previous part of this paper. In these 85 cases I have performed 31 ligations, 19 hemithyroidectomies; in 17 the right lobe was removed with ligation of the vessels on the left; in 18 the major portions of both lobes, leaving a bit of the upper or lower poles, and a posterior strip of the gland. Double partial lobectomy is, in my opinion, a more severe and bloody operation than hemithyroidectomy; but as I look over my cases I feel that more immediate improvement takes place, and the danger of recurrence of symptoms is less. The most difficult question to determine when once operation has been decided upon, is between preliminary ligation of vessels, or removal of portions of the gland. Upon this question different surgeons are not in agreement. A majority, I believe, feel that in the severer cases a preliminary operation of ligation, usually under local anesthesia, makes a subsequent thyroidectomy less dangerous. Whoever has done a secondary operation on these cases is convinced of two things,—that ligation makes the operation somewhat harder, owing to adhesions, and secondly that the ligation of the superior vessels has not much diminished the vascularity of the gland. I think the benefit which frequently follows is due to division of the sympathetic nerves accompanying the vessels. In two cases only has ligation of the superior vessels been sufficient to bring about a cure; after it there has usually been either no perceptible improvement or a period of improvement followed by recurrence. It should be remembered, strictly as a preliminary operation and second, at varying periods, be followed by further operation. In a number of my cases, before the patients would consent, intervals of six months to three years have elapsed, at which time the element of safety after ligation was not established. In such cases, therefore, I consider, if they are severe, that the vessels should be ligated before the thyroidectomy is attempted. For the future of the operation, I have decided to be according to the following plan: In the severe cases, the vessels should be ligated first, or the vessels and a portion of the gland removed. In the moderate cases, the vessels should be ligated first, and the gland removed at a later date. In the mild cases, the gland should be removed at once.

After a preliminary operation of ligation, the patient should be kept in bed for a few days, and the wound should be dressed with a sterile dressing. The patient should be kept in bed for a few days, and the wound should be dressed with a sterile dressing. The patient should be kept in bed for a few days, and the wound should be dressed with a sterile dressing.

tophobia and confinement in a dark room for three months. Ligation was simple, but in spite of all treatment, death with all the characteristic symptoms, occurred at the end of three days. This was a desperate risk taken deliberately. Of the four other cases the operation was a primary lobectomy; two were in young girls eighteen and twenty-five years; two middle-aged women undergoing the menopause.

The one aged eighteen deceived me in her degree of toxicity. Right hemithyroidectomy with ligation of the left vessels was performed under ether, in 1910, and was followed by a typical toxic death in three days. The one aged twenty-five was a very toxic case; had been sick for eight years, and did not improve under three weeks in bed with rest treatment; in fact, on the whole, seemed worse. Right hemithyroidectomy, under gas and oxygen with ligation of the vessels on the left was performed; operation comparatively easy; died on the third day of typical toxemia.

A girl of thirty had extreme symptoms for two years; was unable to work for a year; fell exhausted on the street several times; treated in medical ward without improvement; heart irregular; marked systolic murmur with some enlargement. Right hemithyroidectomy under gas and oxygen, and partial left thyroidectomy were performed with extreme reaction, which persisted unusually long, leaving marked condition of prostration; patient died nine days after operation. All of these three were early cases, and at present I believe that a preliminary ligation should have been done, or the patients should have had x-ray treatment previous to operation.

A Jewish woman of forty, undergoing the menopause, suicidal for a year, refused operation four successive mornings. Finally she consented to it if I would perform it in the afternoon. Rather against my judgment, at the earnest solicitation of her husband, I agreed to do it, under gas and oxygen, removing the right lobe and half of the left. There was considerable bleeding, and with excessively rapid pulse the patient died in three hours. This was in 1909, and did much to influence me against operation. I have broken this rule since then once or twice, always to my regret, and with a severe operative, though not fatal, toxemia; until in March of this year I had another death, the first since 1912. A Jewess of 47 had been ill for five years with nervousness, headache, irregular menstruation, edema and dyspnea, pain in the upper abdomen, rapid pulse, with some enlargement of the heart, some glycosuria, unable to work. Under careful medical treatment for two and a half weeks, she lost seven pounds, and tachycardia and nervousness persisted. I advised ligation under local anesthesia as a preliminary. She had her morphia in two doses and was apparently drowsy, but before operation could be begun she jumped up from the table and insisted upon going home. Three days

later she consented, provided her daughter was present, to have operation under gas and oxygen. I performed a double partial lobectomy without difficulty, but from the time of her recovery from the anesthesia, extremely rapid pulse with excessive nervousness began, and increased until death, at the end of forty-eight hours. This illustrates strikingly, I think, a bad risk in a woman who was steadily running downhill. Operation undertaken was the only hope, and owing to lack of control, toxemia started before operation, and was only increased by it—I think it an error of judgment in attempting to benefit a patient unwilling to accept one's best advice. In four cases severe bronchitis, pneumonia or bronchopneumonia, for reasons which I cannot explain, ended fatally in from a week to a month. In the latter long case the ultimate cause of death was heat prostration in the severe July of 1911. A fifth case died, so far as could be made out, from a terminal pneumonia, aided probably by unsuspected morphinism. Why pulmonary complications should have occurred in these cases and been absent in the non-toxic goitres, it is impossible for me to explain. Another death, similar to a case of Dr. Judd's in Rochester, I cannot understand. Autopsy showed purulent pericarditis, enlarged thymus and adrenals, as a cause of death thirty-six hours after a simple ligation with a clean wound. In another, a large infarct of the right lung, after a very satisfactory gas and oxygen thyroidectomy, caused death on the third day. In this series of 185 cases, there was one instance of tetany—the first post-operative case at the Massachusetts General Hospital. A young girl of eighteen, with severe Graves' disease, had double ligation under ether in 1911, followed by marked improvement which lasted for almost two years—then recurrence of symptoms. Under gas and oxygen in October, 1914, right hemithyroidectomy and partial left lobectomy were performed. The operation was apparently intra capsular. On the fourth day characteristic tetany developed, which was controlled with calcium lactate. In spite of parathyroid tablets and continued calcium lactate, severe convulsions occurred, followed in January, 1915, by acute mania and death. It seems to me necessary to believe that in this instance the blood supply of the upper parathyroids was cut off by the ligation, or the unfortunate patient had an abnormally small number, for the operation was performed in such a manner that some of the parathyroids under normal circumstances must have been conserved. Thus this analysis seems to show that the danger of toxemia is diminished by preliminary ligation a short time previous to thyroidectomy; that perfect control of these patients is necessary, lacking which operation should not be performed. There has been no death from pulmonary complications following local anesthesia. The ease of pul-

monary infarct and purulent pericarditis seems to me to be impossible to avoid.

In endeavoring to analyze the good results of operation, it is most difficult to make satisfactory statistics. Those who have seen the very marked relief within a few days which follows lobectomy, are absolutely convinced that the thyroid *has to do* with Graves' disease. On the other hand, there are occasional cases which, in spite of ligature and lobectomy, disappoint us with their lack of improvement. Some surgeons believe that the thymus gland is in part responsible for the symptoms, and state that improvement has finally taken place after thymectomy. With this operation I have had no personal experience. I am inclined to believe, however, that the failure distinctly to improve or cure a majority of these cases is due to delay in operating until permanent degenerations have taken place, or some not understood action of the sympathetic nerves or other glands in the body.

I have operated upon some quite desperate cases with marked improvement. One, a young girl, with congenital heart murmurs who, it was decided, could not survive the cardiac lesion plus the toxemia of Graves' disease, has been practically cured, as far as any toxemia is concerned, by preliminary ligation, followed later by thyroidectomy. Another woman who was bedridden with coincident mitral insufficiency and severe Graves' disease, is now entirely cured of all her Graves' symptoms, except slight exophthalmos. Another middle-aged woman, bedridden, with marked edema and rapid, irregular pulse, has, after operation, improved so that she can do her work, though some tachycardia and irregularity of the heart persist. Another woman of fifty-five, confined in an asylum, much to my surprise became almost normal after operation; was able to look after herself and go to the theatre alone; dying suddenly of pneumonia a year afterwards. In my experience, the cases which have had exophthalmos for any length of time never again have normal eyes, and not a few of the cases apparently cured under normal circumstances show, under excessive fatigue or worry, slight tachycardia and tremor. Of the 85 cases, 20 are absolutely cured, 18 much improved, 13 improved, 1 not improved and require further operation; 16 have not reported, or done so in too general terms to be valuable for statistics. If then, after a patient has had a reasonable course of rest, medical treatment and x-ray treatment (if it proves to be really and permanently satisfactory), the symptoms persist, operation should be advised. Among wage-earners, who cannot give up the time, and in the chronic cases, in which the disease has advanced too far to allow of delay, after preliminary rest, operation should be performed. Whether this be a preliminary ligation, or lobectomy under local or general anesthesia, must be determined in each

case. Finally, in chronic cases in which there is doubt as to whether the patient is suffering from existing toxemia or has been poisoned irreparably by the disease, modern tests, of which basal metabolism is probably the most important, will aid the surgeon much in deciding for or against operation.

## II.

### RECENT ADVANCES IN OUR KNOWLEDGE OF THE ACTIVE CONSTITUENT IN THE THYROID, ITS CHEMICAL NATURE AND FUNCTION.

By EDWARD C. KENDALL, Ph.D.

*The Mayo Foundation, Rochester, Minn.*

ABOUT eighteen months ago I reported the isolation from the thyroid of a crystalline compound containing 60% of iodine. Since that time I have perfected the method for its isolation, and to some extent have studied its chemical properties and functions. The work may be briefly summarized as follows:

The compound was first isolated in crystalline form in 1914. The work just prior to the isolation had been accomplished with such smoothness and success that no difficulty was anticipated in repeating it, but despite most persistent efforts, no more crystals were isolated until August, 1915. Again it seemed that the isolation had been perfected, but try as we would, no more crystals were seen until February, 1916. This failure occurred in spite of the fact that

the work was vigorously carried on, more than a ton of thyroid being used. It was found by accident that carbon dioxide plays a most important rôle. When I first obtained the substance I was working in a room next to a freezing microtome, and the necessary carbon dioxide was supplied from this source. Later the work was carried on in a room free from excessive carbon dioxide, and crystals were not obtained until it was accidentally discovered that carbon dioxide is necessary.

The reason for the delay and difficulties in this problem lies in the fact that the substance does not exist in a free form in the thyroid secretion, but is firmly locked into the protein molecule. This bond is so secure that it will withstand very vigorous chemical treatment. It is very resistant and the compound is not easily destroyed, but under other conditions simply dissolving will result in the destruction of the compound. The explanation of this behavior lies in the fact that carbon dioxide exerts a peculiar and unique action on the bond that ties the iodine compound within the protein molecule. In short, this bond, which will resist heating with

50% sodium hydroxide, is broken by carbon dioxide and the iodine compound is set free. Having once been liberated from the rest of the protein constituents, its chemical properties permit of very easy separation.

Having separated the crystalline compound containing 60% of iodine from the thyroid, several questions arise as to the relation of this compound and thyroid activity. Thyroid activity can be followed experimentally and clinically, in five broad aspects, namely, the effect on growth, on the mentality, the skin, the hemoglobin, and, greatest of all, the effect on metabolism, and, incident to this, the effect on the heart. It seems indisputable that all of the effects produced by the thyroid are through its effect on metabolism. The combustion of proteins, fats and carbohydrates is increased by the administration of thyroid substance, and it is probable that the various clinical effects produced are due to increase in metabolism through the entire body. The heart rate is increased because of the increased metabolism, and the increased action of the heart is due to

FIG. 16.—Ventricular fibrillation before 100%  $\text{CO}_2$ .

brain cells; the condition of the skin is improved because metabolism within the skin cells is increased; and so it is through the entire body. We have experimented with this substance on animals and have obtained a large number of results from clinical observations. It appears that the entire activity of the gland is manifested by the administration of this crystalline compound alone. There appears to be no other substance in the thyroid secretion which acts directly. This substance, given even in very small amounts, will supplant thyroid activity, relieving the conditions of myxedema and cretinism, and in excess will produce symptoms simulating exophthalmic goitre. It appears to have no direct action on the pulse rate. The extent to which the rate is affected depends not upon the administration of the thyroid, but upon the simultaneous ingestion of food, and in particular of amino acids. This effect may be outlined as follows:

After the administration of the compound, there is no apparent effect for many hours. There is no increased pulse rate, nor drop in blood pressure. However, if the thyroid hormone and amino acids are injected simultaneously, the pulse rate is enormously affected, and even death may result, due to the apparently great increase in metabolism going on in the animal. It appears very probable that the thyroid hormone manifests its activity by reacting in some way with amino acids. The accompanying are typical pictures, which illustrate the effect on myxedema and cretinism, on the mentality, on the skin, and the great emaciation with a toxic effect on the heart after long-continued injection.

### III.

#### CONDITIONS AFFECTING SECRETION OF THE THYROID GLAND.

By W. B. CANNON, M.D., BOSTON.

[From the Laboratory of Physiology, Harvard University.]

A STUDY of the conditions of activity in the ductless glands, which pass their secretions into the blood stream, is difficult because recognition of the secretion in the blood is uncertain or impossible. It has long been known that physiological activity is accompanied by the development of an electrical difference, which may be manifested by connecting an active part with an inactive part through a delicate galvanometer. It seemed possible that by the application of this method important information might be obtained as to the conditions of activity of the ductless glands. This work has been carried on through the coöperation of Mr. McKeen Cattell.

The method was first justified by applying it to the submaxillary gland, which has an external secretion. Because an electrical change ac-

companies the secretion of saliva, even though the blood supply is shut off from the gland or the flow through the duct is stopped; and because the change is absent when secretion is absent, although each of the conditions attendant on secretion—such as contraction of blood vessels, relaxation of blood vessels, faster flow of blood, slower flow of blood—may severally be induced, the conclusion is drawn that the electrical change is a manifestation solely of the process of secretion.

The method thus justified on the submaxillary gland has been applied to the thyroid. Histologists have described nerve fibres leading to the cells of this gland, and anatomists have reported that the fibres going to the thyroid gland arise in the cervical sympathetic ganglia. Previous investigators have shown that severance of its cervical sympathetic nerves causes atrophy of the thyroid, and stimulation of these nerves causes a diminished iodine content of the gland. Severance of the vagus nerve supply has no effect.

If the thyroid gland and neighboring indifferent tissues are connected through a galvanometer, stimulation of the sympathetic strand high in the thorax evokes an action current after a latent period, varying usually between 5 and 7 seconds. This effect persists after the superior and the recurrent laryngeal nerves are severed. Experiments have shown that the nerve impulses pass out through both the superior and inferior cervical ganglia.

Stimulation of the main trunk of the vagus nerve in a curarized animal, or injection of pilocarpine (which excites vagus endings), has no effect in producing an action current in the thyroid gland.

The influence of sympathetic impulses is not indirect, through local anemia of the gland, for when the blood supply is wholly stopped by clamping the blood vessels for a period equal to that of sympathetic stimulation, no noteworthy electrical change is produced.

The conclusion is drawn, therefore, that the nerves distributed to the thyroid cells belong to the sympathetic and not to the vagus supply, and that their effects are not indirect through alterations of blood flow; indeed, that they are true secretory nerves.

It is known that the internal secretion of the adrenal gland, or adrenin, will have the same effect in the body as sympathetic nerve impulses. Injection of a small dose of adrenin, 0.1 to 0.2 cc. (1:100,000), evokes a marked action current in the thyroid gland. Also, stimulation of the nerves to the adrenal glands, so as to cause their secretion to be poured into the blood stream, will evoke a characteristic electrical change in the thyroid. This electrical change does not occur if the return of blood from the abdomen is prevented, but takes place promptly when the pent blood is released. Furthermore, it fails to appear after stimulating these nerves, if the adrenal glands have been previously re-

moved. There is thus definitely established an influence of adrenal secretion on thyroid activity.

This conclusion has been confirmed by the observations of Dr. Robert L. Levy, working in the Harvard Laboratory. He has found that both stimulation of the cervical sympathetic trunk and injection of stimulating doses of adrenin greatly augment the effects of small doses of adrenin in raising blood pressure. This increase of efficacy of adrenin is not produced if the thyroid glands have previously been removed.

Studies on conditions of activity of the adrenal glands have shown that during emotional excitement they secrete into the blood a substance which affects the bodily organs in a manner stimulating the nervous influences of strong emotions. These glands have a routine function, without which certain bodily processes are not normal. They may also be reasonably regarded as having a normal *emergency* function, which is exercised in times of emotional stress, and is important under such circumstances for the needs of the organism, for example, in struggle. This conception of an emergency function gives meaning to the liberation of sugar in the blood, abolition of muscular fatigue, dilatation of bronchioles, inhibition of digestion, redistribution of blood in the body, and rapid coagulation—all changes attending great excitement.

If we conceive the organs disturbed in emotional stress as being protected from such disturbance by a high neurone threshold, requiring great excitation in the central nervous system before the threshold may be crossed, we can account for persistent disturbance of these organs in pathological cases on the basis of a wearing down of the threshold through great or repeated emotional disturbances. Thus there might be gaps here and there in the wall that protects the organs from being over-excited. Under such circumstances, even slight central disturbances might result in persistent stimulation of organs normally brought into action only when such action would be useful, *i.e.*, in times of emotional excitement, when struggle might be essential. If a certain region, *e.g.*, the cervical sympathetic, is thus persistently stimulated by experimental means, most of the phenomena of exophthalmic goitre may be produced. This concept offers an explanation for emotional tachycardia, emotional dyspepsia and perhaps other conditions which present a history of previous great worry or emotional stress.

To test the effect of over-stimulation in a particular region of the sympathetic system, Dr. C. A. L. Binger and I, about two years ago, fused in the cat the anterior root of the right phrenic nerve with the right cervical sympathetic strand. Thus, after regeneration had occurred, there was delivered to the neurones in the superior cervical ganglion a volley of im-

pulses every time the animal breathed. The operations were performed early in May. In October, 4 of the 6 animals were still alive. All had peculiar symptoms. There was marked tachycardia,—the average heart rate in normal cats is about 150 per minute, in 30 observations on these animals it was 222. Though fed like normal animals, they had loose movements of the bowels. They were unusually excitable, as indicated by rushing away when taken in hand or petted. The basal metabolism, as determined by Dr. Reginald Fitz, working in the Carnegie Nutrition Laboratory, was found in normal cats to be approximately 31 calories per square meter of body surface per hour. In 3 of the 4 animals in which the operation had been performed, the metabolism was much elevated. In one of them (in all ways the most profoundly altered animal) it rose to an average of 72 calories per square meter per hour,—an increase over 130% above the normal average. In others the rise was approximately 100%. In two animals that died of the disease, the adrenal glands were found much increased in weight. In one of them the glands were three times the average weight, the increase being chiefly in cortical substance. One of the animals had definite exophthalmos and respiratory oscillations of the pupil on the operated side. These symptoms are, in the main, characteristic of exophthalmic goitre as seen in man.

Since these first observations, the disease has been produced in another animal, and it has been proved that the symptoms, rapid heart, increased excitability, steadily mounting metabolism, with loss of weight—all disappear on the removal of the thyroid gland on the operated side. The metabolism, which had increased approximately 100%, dropped down to within normal limits. Whereas the other animal living the induced disease had died within three months of the first appearance of the symptoms, this animal lived normally for six months after the operation and then died of pneumonia, killed.

The thyroid gland of the animal that lived six months after the operation was found to be of the average size and weight of the normal gland. It was found to be normal in all respects, and the animal lived normally for six months after the operation and then died of pneumonia, killed.

## IV.

## THE CLINICAL VALUE OF METABOLIC STUDIES OF THYROID CASES.

BY WALTER M. BOOTHBY, M.D., BOSTON.

[From the Surgical Service and Respiration Laboratory of the Peter Bent Brigham Hospital, Boston.]

THE brilliant researches of Lavoisier on the nature of oxygen, carbon dioxide, and heat led him to propound the fundamental proposition that the life processes were those of oxidation with the production of heat,—and thus to found the science of metabolism.

Since then it has been demonstrated that the complete combustion of substances in the body is not only qualitatively, but quantitatively, identical with the burning of those substances outside the body. Consequently it is now possible to calculate the amount of heat produced by the metabolic processes from a knowledge of the oxygen consumed and the carbon dioxide eliminated in a given time.

For clinical purposes these factors for calculating the heat-production can be determined with a high degree of accuracy by collecting, measuring, and analyzing the expired air.

In order to compare the heat production of one patient with that of another, it is necessary to eliminate such disturbing factors as muscular activity and the stimulating action of food. Hence absolute rest and abstinence from any nourishment for at least twelve hours before the determination are essential. The heat-production obtained under these conditions is known as *basal metabolism*.

The general application in the clinic of metabolic data has not, until very recently, been of much practical value, because the comparative standards used showed wide variations in the basal metabolism of normal people. This problem is not even now completely solved, but DuBois<sup>1</sup> has shown that, when compared by surface area determined by a height-weight curve proposed by him, the basal metabolism of normal people rarely varies more than ten per cent. from an average figure, the latter depending on age and sex.

Some six hundred determinations of the basal metabolism have been made on one hundred and forty patients during the past year in the Respiration Laboratory of the Peter Bent Brigham Hospital. The cases studied have been those in which chronic metabolic disorders were a possible factor in the production of the symptom-complex, as well as a considerable proportion of traumatic and miscellaneous cases for comparison.

We have found that convalescent, post-operative cases of acute appendicitis, hernia, varicose veins, alveolar abscess, and similar conditions, with normal temperature, after varying periods of recumbency, have shown, with one exception, a basal metabolism which does not vary more than ten per cent. from Du Bois' normal, and in

the majority of cases the metabolism is within five per cent. of his normal figure.

The patients in whom we have found an abnormal variation in the basal metabolism are those in whom involvement of an endocrine organ could either be established or considered as a possibility.

The endocrine organs furnish a series of substances, designated by Schaefer<sup>2</sup> as autacoids, which enter into the blood stream and act on certain body cells, either exciting or depressing their functions. For normal metabolism, Paton<sup>3</sup> believes that a certain amount of each autacoid is essential and that some proportion between the amounts of each must be maintained.

Abnormal variations in the amount of some of these autacoids are known to speed up or to slow certain cell activities, producing definite pathological conditions with a corresponding alteration in the basal metabolism. It has been possible, therefore, to explain many metabolic diseases like myxedema, acromegaly, and exophthalmic goitre, by alterations in the quantity or character of the secretion produced by an endocrine organ.

No factors other than the autacoids have yet been discovered which are known to influence basal metabolism, with the possible exception of the toxins in fevers. Therefore it seems logical to reverse the accepted theory and, except in the case of infections, to suggest the tentative hypothesis that a variation of the basal metabolism beyond normal limits is due to an abnormality in the secretion of one or more of the endocrine organs. The particular autacoid must then be sought for by characteristic localizing symptoms and by the elimination of those autacoids, variations of which produce well-known signs and symptoms.

This hypothesis allows a clear-cut division to be made between diseases in which the metabolism is increased, decreased, or remains normal, together with the probable cause of the disordered metabolism. Such a division is fundamental because it is made on an accurate knowledge of the rate at which the body cells are actually living. It will, therefore, serve as a foundation on which the subsidiary objective and subjective symptoms can be superadded, thus aiding in differentiating into distinct disease entities some of the present confused clinico-pathological groups, like the anemias and chronic nephritis. In both of these ill-defined groups we have found, as might be expected, marked divergence in the metabolic findings. Such variations are not to be looked upon as accidental or inconsequential—they must be considered as absolutely fundamental.

Important as is the diagnostic value of metabolic studies in endocrine disorders, of no less importance is their value in determining the proper method of treatment, since conditions of over- or under-activity require different therapeutic measures. The determination of the

basal metabolism before, during, and after treatment, will give in mathematical terms, easily understood, the value of that treatment. It will indicate whether the procedure has been beneficial or, on the other hand, harmful.

Diseases of the thyroid gland, with their extreme variations in the basal metabolism, afford a most striking example of the significance of metabolic studies. Furthermore, the connecting link between the etiological cause and the clinical picture is, in these diseases, most evident. In conditions of thyroid overactivity the metabolism may increase to one hundred per cent. above normal, and in conditions of underactivity it may be decreased to fifty per cent. below normal. Moreover, we have found that the patient's condition, judging from the sum total of the objective and subjective symptoms, corresponds very strikingly to the numerical expression of the basal metabolism.

The following case is illustrative.

C. W., aged 23, candy dipper, unmarried. Entered the hospital June, 1915, for chronic appendicitis. At that time the thyroid gland was described as somewhat enlarged but no constitutional symptoms were noted. In February, 1916, she re-entered complaining principally of swelling of the neck with very slight pressure symptoms. There had been progressive loss of weight from 125 to 105 pounds. Her skin was moist and red. She had slight psychic symptoms. The eye symptoms were practically negative, there being only a questionable exophthalmos. The slight tremor of fingers and tongue present increased under excitement. Her pulse was not particularly rapid, being seventy at rest, although it increased markedly on exertion. There was fullness of the neck and the thyroid lobes were palpable, but there were no thrills or bruit. The basal metabolism at this time was twenty-eight per cent. above normal. Partial thyroidectomy resulted in (Dr. Jacobson) improvement in the clinical symptoms. Patient was discharged eight days after operation. Her metabolism had then become normal. She returned to work and on re-examination six weeks later the metabolic findings were still normal.

In this case the diagnosis lay between a small colloid non-toxic goitre in a patient with slight nervous temperament from other causes and the early stages of a mild type of toxic non-exophthalmic goitre. The latter interpretation was definitely made by the metabolism studies, which showed an increase to twenty-eight per cent. above normal. Immediate operation was therefore advised; expectant treatment would have been permissible only if the metabolism had been normal. The operation was done consequently before the thyroid toxemia had produced any profound and long-lasting constitutional disturbances; hence recovery was correspondingly prompt and no long post-operative rest was necessary for recuperation.

No such rapid recovery occurs in patients in whom the thyroid intoxication has been of sufficiently long duration to produce profound secondary constitutional disturbances.

The following case illustrates a slow but complete recovery:

A. J., aged 33, housewife, entered hospital in September, 1915, presenting symptoms of moderately severe exophthalmic goitre of at least eleven months' duration. The basal metabolism was determined and found to be thirty-five per cent. above normal. Partial thyroidectomy (Dr. Homans) resulted in a general clinical improvement and fourteen days after operation the metabolism decreased from thirty-five to twenty per cent. above normal. After discharge from the hospital the patient went South and rested for two months in bed; she gradually increased her exercise and in another month considered herself well, excepting that she was then subject to debilitating attacks of tonsillitis. Seven months after operation she returned for examination and the metabolism was found to be normal and she appeared in every way completely cured.

In some instances complete recovery may not occur because too small an amount of the gland is removed. This is most likely to occur in the especially severe cases, whose precarious condition prevents a more extensive operation. Repeated metabolism studies will determine when the full extent of the improvement is reached, and thus furnish definite information both as to the necessity and the opportune time for the subsequent operation.

M. D., aged 21, married. Entered the hospital in March, 1916, with symptoms of very severe exophthalmic goitre. Her metabolism was determined and found to be ninety-eight per cent. above normal. Rest in bed for four weeks resulted in almost no improvement, the metabolism then being eighty-nine per cent. above normal. Partial thyroidectomy (Dr. Chace) resulted in considerable improvement. The metabolism increased to sixty-seven per cent. above normal. Patient was then discharged. After her return home she failed to rest and in addition had a very severe attack of tonsillitis. Six weeks after discharge she returned for examination. Her metabolism was found to be still very high—fifty-four per cent. above normal.

It is too early to predict the outcome of this case; it seems unlikely, however, that simple rest treatment will be sufficient. She is, however, naturally anxious to avoid a second operation; delay is advisable as long as improvement continues,—an improvement definitely determined by metabolic studies at frequent intervals.

This patient, as well as several others, received no benefit from simple rest treatment. In one case even showed an increase in metabolism.

A. E. H., aged 32, married, entered hospital in 1915, with symptoms of severe exophthalmic goitre, accompanied by a moderate degree of infection. The basal metabolism was determined and found to be fifty per cent. above normal. After operation the metabolism decreased to thirty per cent. above normal. Patient was discharged. After her return home she failed to rest and in addition had a very severe attack of tonsillitis. Six weeks after discharge she returned for examination. Her metabolism was found to be still very high—fifty-four per cent. above normal.

further rest together with x-ray treatment, the metabolism decreased to thirty-six per cent. above normal. He was then discharged and was shortly able to go to work; by letter he reports that he is doing well and is gradually getting stronger.

This patient, like A. J., probably would become entirely well under prolonged rest treatment. But he could not afford this. Economic conditions may, therefore, suggest the advisability of a second operation on those cases whose metabolism remains elevated and whose financial condition prevents prolonged rest.

The following case illustrates the opposite type of thyroid dystrophy.

M. J. B., aged 62, unmarried. Entered February, 1916. There was marked edema of the eyelids and moderate edema of the extremities. The skin was dry, but not especially thickened; almost complete loss of hair. The temperature, pulse, and respiration were subnormal, and patient was exceedingly drowsy. Urine, acid, 1.015; very slight traces of albumin; no sugar, few squamous and white blood cells; occasional red blood cells; and a few finely granular casts. Special renal tests showed very low function. Metabolism very markedly decreased to forty-seven per cent. below normal.

Under intermittent small doses of thyroid, the patient very slowly improved. Within two months metabolism had increased from forty-seven per cent. to fifteen per cent. below normal. Thyroid was then discontinued as patient was showing signs of irritability.

One month later the metabolism was again determined and found to be slightly lower—twenty-two per cent. below normal.

The clinical improvement in this patient from thyroid treatment was most marked and exceedingly striking. The albumin and casts have disappeared from the urine, and there has been some improvement in the renal function tests.

This case is most suggestive because two clinical entities were apparently present,—the myxedema and the chronic nephritis. Under thyroid treatment the myxedema greatly improved; likewise the albumin and the casts disappeared from the urine. The thyroid autacoid probably plays a very important part in regulating the protein metabolism, some of the steps of which Kendall<sup>1</sup> has recently been able to point out. It is not improbable, as in the above case, that a mild condition of myxedema may sometimes be mistaken for a chronic nephritis; in doubtful cases, therefore, the determination of the basal metabolism would materially assist in establishing the correct diagnosis.

#### SUMMARY.

1. Basal metabolism for clinical purposes can be obtained with a high degree of accuracy by collecting, measuring, and analyzing the expired air.

2. In normal people the basal metabolism rarely varies more than ten per cent. from a

normal figure, depending on age and sex, when compared by surface area, determined by DuBois' height-weight curve.

3. Several cases of thyroid dystrophies, in which the basal metabolism was determined, are cited to illustrate its value in diagnosis and in determining the proper method of treatment.

### PARTIAL THYROIDECTOMY WITH LOCAL ANESTHESIA, SCOPOLAMINE AND MORPHIA.

By FRANK H. LAHEY, M.D., BOSTON.

MANY of the factors in the production of exophthalmic goitre are gradually having light thrown on them by men like Dr. Kendall and similar painstaking investigators, and the knowledge gained of other ductless glands, owing to the interdependence of all, has done much to advance our knowledge of processes relating to thyroid functioning. The subject of ductless glands involves so many different fields,—chemistry, physiology, and pathology,—that other than for a trained investigator, or one interested enough in the subject to digest it patiently, the following and comprehension of the literature relating to investigations on these glands is not an easy thing. Therefore, you as clinicians may rightly say: "For us it is sufficient that the disease exists. What shall we do for it?" My answer would be, "surgery," in the light of all experience up to the present time.

The disease, untreated, has a very definite mortality,—stated by some radical writers as high as 29% in cases observed over a period of ten years,—and results in the remainder in varying degrees of incapacity and discomfort. A small percentage of cases result in spontaneous cures. Surgery offers a mortality of from 2 to 7% and a percentage of cures of from 50 to 70%, and improvement in from 20 to 30% of the remainder. To my mind there is no question that surgery offers by far the quickest and surest way to recovery. Comparing the mortality of untreated with the operated cases, it is my opinion that, even accepting the high mortality mark of 7%, the eventual risk is less with operation than with medical treatment.

Having demonstrated to myself that surgery is the treatment of choice in these cases, it became my aim to reduce the mortality of that method of treatment to its lowest possible point in my hands. So, after the occurrence of two

the right side, the gland turned bottom side up, and the capsule demonstrated and pulled away from the outer edge of the gland.

*Slide V.* Shows how the cut surface of the gland is sutured over.

*Slide VI.* Shows the relation of the portion of gland left to the whole gland.

*Slide VII.* Is a drawing of a dissection of the gland made under my direction, showing the relation of the posterior surface of the gland to the recurrent laryngeal nerves, the course of the inferior thyroid artery from behind the common carotid up to its insertion into the gland and the relation of the thyroidea ima artery to the gland.

## THE TREATMENT OF GRAVES' DISEASE BY THE ROENTGEN RAY.

BY MALCOLM SEYMOUR, M.D., BOSTON.

[From the Medical Service of the Massachusetts General Hospital.]

THE treatment of Graves' disease by the roentgen ray has been used for many years. Uniform results have not been obtained until recently. This has been due to the inaccuracy in dosage, resulting either in no action or in serious burns, so that the treatment has been unsatisfactory and often dangerous.

The action of the roentgen ray on some of the ductless glands of the body has been observed for a long time. Its effect on the testicle and ovary is now common knowledge among the profession. Its atrophic action on the thyroid, thymus and pineal has recently received considerable study.

It is a well-established fact, that the highly specialized epithelial cells are the first to succumb to the action of the roentgen ray, and, furthermore, the more closely these cells approach the embryonal type, the more easily is their destruction accomplished. Therefore, when the pathological histogenesis of the thyroid and thymus gland in Graves' disease is borne in mind, it can readily be seen that in the roentgen ray we possess a therapeutic agent of undoubted efficacy in the treatment of this disease. This is further borne out by the large number of cases in Europe and America that have been successfully treated by men who are thoroughly familiar with the technique of roentgen therapy. F. A. Stoner treated 41 cases, with only one failure. Some of these cases were under observation from one to four years, with no sign of returning symptoms.

Ludin collected 208 articles on this subject, showing that the roentgen ray had a favorable influence on Graves' disease. In general, it was found that the longer the duration of the symptoms, the more treatment was required to cause their abatement and disappearance. He also

found that there was little foundation in fact for the claim that the rays caused such changes in the capsules of the glands that made operation difficult. It is now being noted, that frequently operations for thyroidectomy are complicated by so-called thymus deaths or status lymphaticus. Most surgeons insist that the thymus should be investigated and resected at time of operation so as to prevent the above condition.

We have, at the present time, under treatment at the Massachusetts General Hospital, 144 cases of Graves' disease. Treatment of most of these cases has been going on since August 1, 1915. Of these 144 cases, 80 have been given at least two treatments. The average number of treatments received has been four. The duration of the treatments has been from two to eight months, the average being three and one half months. Of the 80 cases which have been treated, all have shown improvement with the exception of seven. Of these seven cases, three have received two treatments, three have received three treatments, and one has received four treatments. In one of these cases the disease is complicated by asthma, and one has active pulmonary tuberculosis. Five cases showed no change. Four were born in Russia, and although the pulse rate is lowered and the tremor has largely disappeared, they will not admit that they are improved, and complain of indefinite aches and pains throughout the body. One case has had three treatments, and shows absolutely no change. Of the eighty cases, eight were absolutely cured of their symptoms. Nearly all have gained in weight. The average gain has been seven pounds, one case having gained twenty-five pounds. The pulse rate has been lowered in all but a few cases, the average being twelve beats. The greatest lowering in pulse rate was 52 beats, from 146 to 94. In this patient, the symptoms were very severe, with marked exophthalmos and tremor, and a moderately enlarged tumor of the gland. She had five treatments. The tremor has disappeared, the exophthalmos has practically gone, the circumference of the neck decreased one-half inch, and she feels perfectly well.

The method of treatment has been as follows: The neck has been divided into three areas,—right, left and middle or suprasternal,—and the treatment directed to these areas. A Coolidge tube has been used. The average dosage has amounted to about 4 II., which equals 5 Holzknecht or 10x Kienbock or 13 Salmonaud-Noire. This is the dose necessary to produce a slight erythema. Some writers state that an erythema dose is too severe, but we have not found this to be so. It seems advisable, however, to keep just below the erythema dose so as not to cause any skin irritation, inasmuch as it seems evident that repeated erythematous doses may cause vessel changes in the skin covering the tumor, or the tumor itself.

In all cases, the target of the tube was at a distance of 10 inches from the skin, and a filter of 4 mm. of aluminum and 1 thickness of sole leather was interposed. The dose has not been repeated inside of three or four weeks. Under general treatment, most of the patients have not changed their modes of living, excepting the diet, which has been increased or favorably rearranged, and treatment has been directed towards anemia, which has been present in a considerable number of cases.

The diseases of the thyroid gland have recently been studied with particular interest, since the level of the total metabolism seems to be the best index of the activity of the thyroid secretion. DuBois found in a cretin who was 36 years old, the total energy requirement was from 18 to 25% above the normal, but was raised almost to the normal on the third day of treatment with thyroid extract.

In a recent study of the metabolism of hyperthyroidism, Dr. J. H. Means, of the Massachusetts General Hospital, has found in a series of nine cases of typical exophthalmic goitre, that the metabolism in all of them showed a marked rise, anywhere from 30 to 80% per square meter of body surface, using the DuBois formula for surface area of body, and still more per kg. of body weight, this latter being due to the great emaciation which many of them show.

This marked rise in hyperthyroidism is very interesting because, so far as is known, so marked a rise occurs in no other condition in which fever is not present. These patients were all afebrile when studied.

In addition to the fact that an increased heat production is a characteristic of hyperthyroidism, there seems to be good evidence that the severer the intoxication, the higher the metabolism.

During the study of these cases, our attention necessarily centered on the region of the body nearest the thyroid gland, and in making the routine observations as to size of the gland, etc., various bony abnormalities were encountered. Five cases of extra-cervical ribs were observed among the 144 cases studied, four being found during the physical examination, and one by the x-ray. All were without symptoms which might have been caused by this abnormality.

#### CONCLUSIONS.

All writers on the subject of x-ray treatment of hyperthyroidism have come to the following conclusions: The pulse rate is nearly always reduced, and this, almost always at once. The tremor and nervous symptoms improve from the start. The gland rapidly diminishes in size in some cases, remains unaffected in others, but if hard, tense and throbbing, the throbbing diminishes and the gland becomes softer. The body weight practically always immediately increases.

Advantages of this treatment:

1. There are no fatalities.
2. There is no resulting scar, as after operation.
3. It does not interfere with the patient's occupation.
4. It is painless and causes very little inconvenience to patient.
5. If unsuccessful, an operation may be done with less risk, because of the favorable action of the x-ray on the thymus gland.

The x-ray treatment of Graves' disease should not be undertaken except by those thoroughly experienced in roentgen therapy. The dosage must be accurately measured, for if the rays are applied in a haphazard manner without knowledge of the total dosage, the result may be unsatisfactory, resulting in serious burns or in total destruction of the gland, causing myxedema.

The diagnosis of hyperthyroidism is frequently overlooked, and is mistaken for so-called neurasthenia, and is especially confused with early pulmonary tuberculosis.

#### THE EXCRETION OF HEXAMETHYLENAMIN BY DAMAGED KIDNEYS.\*

By GEORGE GIBBERT SMITH, M.D., BOSTON.

(From the Genito-Urinary Department, Massachusetts General Hospital.)

In the management of renal infections, the medical profession has been accustomed to place considerable confidence in hexamethylenamin. This drug is excreted by the kidney and is broken up by acid urine into ammonia and formaldehyde. Despite the conclusions of some investigators, who allege that the splitting off of formaldehyde does not occur until the urine has reached the bladder, clinical experience has taught some of us that renal infections of the most severe type can be controlled and perhaps cured by the administration of urethane.<sup>1</sup>

It is somewhat disturbing, therefore, to read in a paper by Falk and Sugrue,<sup>2</sup> dated 1920, the statement: "Research conducted by the Rockefeller Foundation has shown that the pathological process of pyelonephritis is characterized by a marked impairment of the excretory function of the kidney, and that the excretion of hexamethylenamin is markedly reduced in such cases." It is not surprising, therefore, that the authors of this paper should have

\*Read before the Boston Society for Medical Progress, April 22, 1922.

<sup>1</sup>See Smith, G. Gibbert, "The Treatment of Renal Infections," *Ann. Surg.*, 1922, 75, 1.

true, urotropin must be placed on the shelf along with the other false hopes of the pharmacopeia.

It seemed to us important to investigate this question. In the first place, upon what evidence do Falk and Sugiura base their conclusions?

They determined the quantity of urotropin by a method which depends upon the precipitation of urotropin by the addition of an alcoholic solution of iodine. This test does not take into consideration the free formaldehyde which may be present (personal communication from Falk).

This seems to us a possible source of error. Some of the specimens were examined by Falk and Sugiura a good many hours (at least 20) after they were voided. During this period, if the urine were acid, a splitting-up of the urotropin present undoubtedly was going on. The writers partially cover this point by saying that if the test for hexamethylenamin is "negative or doubtful, the test is confirmed by acidifying a few cubic centimeters of the solution with sulphuric acid, warming, and then testing with phloroglucin and alkali for formaldehyde." The absence of the latter, they conclude, "proves conclusively the absence of hexamethylenetetramin."

We would answer this point in two ways. First, they apply this acidifying test only when the test for urotropin is "negative or doubtful." If urotropin is present in small quantities, they do not use this control. Secondly, the test for formaldehyde which they employ seems inadequate. In the 40 observations on normal urines given by them, there is one strong test for formaldehyde, one "faint to strong," and three "fair." All the others are faint, very faint or negative. The work of Burnam and my own work upon the question of the presence of formaldehyde in urine gave a much larger proportion of positive results. We used the phenylhydrazine, sodium nitro-prusside and sodium hydrate test; they used the phloroglucin and alkali test.<sup>1</sup> The point is a difficult one to make clear without further data, but it seems that if the test used by Falk and Sugiura gave only 5 positive results out of 40 observations on normal urine, it cannot be relied upon as a control for the excretion of hexamethylenamin.

If the urine to be tested contains albumin, it must be submitted to the following process before the estimation can be made. "An equal volume of methyl alcohol is added, the mixture allowed to stand one or two hours at room temperature, filtered by decantation through folded filter paper, evaporated to one-third the volume in a current of air or under diminished pressure."

It has been shown that urotropin dissolved in acid urine and allowed to stand for several

hours at room temperature will be partly broken up, and that the urine will then give a definite test for free formaldehyde. It seems to us highly probable that during the process of filtering and evaporation, through which albuminous urines are put in Falk and Sugiura's test, the urotropin, at least in part, is converted into formaldehyde, and the latter, being simply a gas in solution, escapes. Urine from damaged kidneys is usually albuminous; it is this urine which is subjected to the preceding test. These investigators do not mention control experiments upon normal urine to prove that the process does not drive off urotropin in the form of formaldehyde; it appears to us justifiable to believe that the test itself, which is not the same for normal and for albuminous urines, may be one cause of the apparently diminished urotropin content in urine from damaged kidneys.

Falk and Sugiura applied their quantitative test for urotropin to the urines of various normal individuals, and found that the ingestion of one gram of urotropin was followed by the excretion in the urine of quantities of the drug varying from 11% to 74% of the amount ingested; that in general the absolute amount of urotropin excreted by the kidneys increased as the specific gravity of the urine decreased. "The lower the specific gravity of the urine, the larger was the amount of hexamethylenetetramin excreted." They do not attempt to explain this phenomenon, but apparently regard it as being connected in some way with the kidney. They do mention the possibility of its being due to differences in the absorption of the drug by the gastro-intestinal tract. To us, this seems to be the explanation. The normal kidney is remarkable for the uniformity of its work; upon this quality the various functional tests depend. To secure uniform results, however, a definite quantity of the substance used must be introduced into the blood-stream; the factor of absorption from the gastro-intestinal tract at once diminishes the accuracy of the test as a measure of renal function.

It is highly improbable that the healthy kidney which excretes the test drugs with such uniformity, behaves in so capricious a manner towards hexamethylenamin. It is highly probable, on the other hand, that varying conditions in the gastro-intestinal tract—the presence of food, the acidity of the gastric juice, the amount of fluid in which the drug is diluted—alter in the same individual the amount of urotropin which is absorbed. Quite possibly the ingestion of much water aids in the absorption of urotropin, thus accounting for the observation that high urotropin excretion and low specific gravity go hand in hand.

The low output of urotropin by some of the pathological cases cited by Falk and Sugiura may be due to conditions affecting the metabolism of the entire body, such as anasarca or a state of impending death, which must have

<sup>1</sup> In my experience, Burnam's test has shown itself three or four times as delicate as the phloroglucin test. This does not agree with the findings of Hanzlik and Collins, who consider phloroglucin the more delicate. (Hanzlik and Collins, *Arch. of Int. Med.*, 1913, Vol. 12, p. 578.)

greatly diminished the absorptive powers of the stomach and intestines.

The output of the drug was studied by Falk and Sugiura in 24 pathological cases. One gram was given, and the urine collected for the next 12 or 24 hours. Nine of the cases (15, 17 to 24) were under treatment for diseases—tuberculosis of the knee, leukemia and syphilis of the brain for example—which had no particular connection with the kidneys; three others, (13, 14, and 16) had arteriosclerosis, which might possibly have had renal manifestations. Of these 12 cases—half the series—there is no evidence presented to show that there existed any real damage of the renal tissue. In three of them, indeed, we are told nothing whatever about the renal condition. Yet of these 12 cases, only two show an output of urotropin greater than 13%. Four of them show only a trace.

The other 12 cases are all renal—one nephropsis, one septic infarct (unilateral), one amyloid kidney. The other nine are chronic interstitial or cardio-renal cases. They excrete urotropin rather better than do the twelve with healthy kidneys—27%, 86%, 79%, 24%, 61% are the five best outputs. Of the others, two who died put out only a trace, and one with a retained nitrogen of 164 and a phthalein test of 0, put out none.

Careful study of this series of observations fails to show any constant relation between the renal condition and the output of urotropin. The amount of urotropin excreted averages less than in the series of healthy kidneys; that may be due to the effect of the test itself when applied to albuminous as contrasted with non-albuminous urines, or may be due to the poor absorptive powers of many of the pathological cases. One would hardly expect a patient in the last stages of leukemia to have a very robust metabolism.

The evidence produced by Falk and Sugiura does not warrant the conclusion that damaged kidneys do not excrete urotropin in sufficient quantity to be of bactericidal value.

In order to test this point still further, we have examined the urines of 14 patients whose kidneys were unquestionably damaged, many of them to a marked degree.

Not being proficient enough to employ the test used by Falk and Sugiura, we have had to rely upon the test for formaldehyde described by Burnam. As a rough measure of the concentration of the formaldehyde, positive urines were diluted until they no longer gave a positive test. The last dilution giving a definitely positive test we took to be a 1:300,000 solution, since formaldehyde added in known quantities to normal urine ceased to give a positive test when diluted beyond this point. By dividing 300,000 by the number of dilutions, the approximate strength of the original solution was arrived at. This method, unfortunately, was suggested only towards the end of the investigation and was employed only in a portion of the cases.

The cases studied fall into two groups:

- (1) the "surgical" kidneys resulting from renal calculus, obstructing prostate, etc., and
- (2) the "medical" nephritis of chronic interstitial or glomerular type.

Ten cases with kidneys damaged by infection were studied. The evidence of bilateral damage was found in the decreased phthalein output plus the clinical history. Seven of them were old men of the prostatic class; one was a bilateral pyelitis, one bilateral renal calculi, one a rather obscure case of a septic infarct or eclamptic kidney. The prostates had been taking urotropin gr. x four times a day for varying periods; the others had been given gr. xv three or four hours before the urine was collected. Of these 10 cases, the urine contained free formaldehyde either before or after boiling with sulphuric acid (depending largely upon the acidity) in quantities sufficient to give a moderately positive test (dark green with Burnam's method) in 4 cases, and a strongly positive test (bluish or blackish green) in 6 cases. Of the strongly positive cases, the strength of formaldehyde present, estimated by the dilution method, was 1:40,000 once, 1:30,000 twice, 1:10,000 three times. The strength of the moderately positive tests was probably not more than 1:60,000 to 1:100,000.

Perhaps the case most strikingly illustrative of the ability of damaged kidneys of this type to excrete urotropin was that of Mrs. L., aged 52, whose x-rays showed huge calculi in both kidneys. After the intramuscular injection of 1 c.c. phenolsulphonephthalein solution, no color appeared in the urine for 35 minutes. In the hour following the appearance of the color, less than 5% of the dye was excreted. She had been taking urotropin gr. xv three times a day for several weeks, and the urine showed a urotropin content of at least one part in 10,000.

From the study of this group of ten cases, all of whom had that type of kidney disease which is usually treated by urotropin, we do not find evidence that the output of urotropin is reduced below the point of efficiency.

Examination of four cases of the nephrotic type, however, gave different results.

CASE 1. Age 58. Chronic nephritis, type 1, with phthalein excretion of 0.000001 after the second hour, not proteinuric. After the administration of one dose of gr. xv urotropin, the urine contained free formaldehyde in a quantity sufficient to give a bluish blue color.

CASE 2. A patient with chronic nephritis, type 1, first seen at the Boston Hospital for Diseases of the Kidney, in 1914, with a phthalein excretion of 0.000001 after the second hour, not proteinuric. After the administration of one dose of gr. xv urotropin, the urine contained free formaldehyde in a quantity sufficient to give a bluish blue color.

CASE 3. Age 58. Chronic nephritis, type 1, with phthalein excretion of 0.000001 after the second hour, not proteinuric. After the administration of one dose of gr. xv urotropin, the urine contained free formaldehyde in a quantity sufficient to give a bluish blue color.

and 74 mgm. non-protein nitrogen, put out only the slightest trace of urotropin 10 hours after a dose of gr. xv, and none at all after two doses 16 and 4 hours previously.

CASE 4. A man of 46, with probable bilateral polycystic kidney, phthalein excretion of less than 5% in two hours, and non-protein nitrogen of 97 mgm., excreted only a small amount of formaldehyde (moderately positive test); this appeared 5 hours after ingestion of the drug.

In a previous paper on the excretion of formalin in the urine, I stated that "the kidneys of chronic nephritis, to judge from a few observations, excrete urotropin much more slowly than do normal kidneys. One dose of grains xv has given traces of formaldehyde in the urine for 36 hours." From the very limited number of cases of nephritis which we have studied in this connection, it would appear that serious disease of the glomeruli greatly decreases the ability of the kidney to excrete hexamethylenamin. If this is true, the diminished excretion of this drug in chronic glomerulo-nephritis should not affect the position of hexamethylenamin in the treatment of renal infections. According to Cabot and Crabtree, colon infection affects the epithelium of the tubules. Excretion of hexamethylenamin by the glomeruli is not interfered with, and the drug, as we have shown, is put out in good quantity.

In view of the above findings, we believe that the statement of Falk and Sugiura in regard to the low output of hexamethylenamin by kidneys with impaired function is of very little practical importance. Close analysis of their paper shows several probable sources of error in their procedure, and these errors all tend to represent the urotropin output as less than it really is. Of the 24 pathological cases studied by them, 12, or one-half the number, fail to present evidence of any value pointing to true renal disease. These 12 cases, furthermore, show a lower output of urotropin than do the 12 cases of renal disease in the same series.

No conclusions as to the value of urotropin in those cases in which it might be expected to do good can be drawn from the work of Falk and Sugiura.

As positive evidence on the question of the output of urotropin by infected kidneys we have presented facts drawn from a study of 10 cases of undoubted renal disease of this type. In every case urotropin was excreted; in three cases, in a strength of 1-10,000; in two, 1-30,000; in one, 1-40,000. It was weaker in the other four, although strong enough to give a definite test with Burnam's method. In chronic nephritis of advanced degree, we have found in three cases a diminution in the output of urotropin which would be a serious factor in its employment as a therapeutic agent. Fortunately, in such cases it need seldom be employed. In kidneys damaged by infection, even to a very marked degree, the drug may be excreted in a strength as high

as 1-10,000. One must bear in mind the very important fact that no matter how much urotropin is excreted, it will be useless as a bactericide unless it is broken up into formaldehyde by urine which is definitely acid.

We wish to acknowledge our indebtedness to Dr. W. Denis, Director of the Chemical Laboratory at the Massachusetts General Hospital, for much valuable assistance, and to the Medical Staff for the use of their cases.

## THE ILEO-CECAL VALVE AND THE CHRONIC INTESTINAL INVALID.

A PRELIMINARY NOTE ON VALVULAR INCOMPETENCE WITH CASE REPORT DEMONSTRATING SUCCESSFUL NON-SURGICAL THERAPY.

BY JOHN BRYANT, M.D., BOSTON.

THE existence of the ileo-cecal valve was first noted by Posthius in 1566; four years later, Varole stated that its function was to prevent regurgitation of faeces into the small intestine. Piccolomini in 1586 produced experimental incompetence of the valve. Good, 336 years later, stated that the second main function of this muscular valve is to moderate the flow of the contents of the small intestine into the colon. After an additional 75 years, Hertz in 1897 recognized clinically the existence of incompetence of the valve, and treated it medically with some success.

Cole, in 1902, demonstrated incompetence by the bismuth-roentgen method, and has since stated that clinical symptoms vary in intensity with the degree of incompetence present. Macewen in 1904, on the basis of direct observation in the human, deduced the existence of the pyloro-ileo-cecal reflex, later proved by the physiologists; he also clearly described a type of indigestion resulting from too rapid passage of food products through the valve, and described the effects of mental states upon its action.

Yet, for the most part, knowledge of the ileo-cecal valve has been conspicuous by its absence. Thus, even standard anatomies of today are content to perpetuate error in the little they do say about it, by dismissing the valve as a purely mechanical affair.

The last three years, however, have seen a renewal of interest in the actions of this small but interesting structure, as witness the writings of Kellogg, Case, Cannon, Elliott, Rutherford, and others. It is at least now proven that the ileo-cecal valve

- I. Is normally competent after infancy.
- II. Should constitute an effective break in continuity between the very dissimilar, even if adjacent, processes of putrefaction and absorption.

- III. Is an active muscular as well as a passive mechanical structure.
- IV. Is responsive to both nervous and chemical stimuli.
- V. Is exposed to possible destructive distensive pressure from above, below, or both.

It is also established that the valve is frequently unable to withstand the strains to which it is subject, since various able roentgenologists have reported it incompetent in the proportion of one case in five.

Also, incompetence, when found, may not be dismissed as harmless and unimportant, or merely as a symptom pointing to something else. It has, on the contrary, been proven by Kellogg and others to be a direct cause of disagreeable symptoms from which the patient may properly expect to obtain at least some measure of relief.

What is the real frequency of incompetence? When found, is it congenital or acquired, and in what proportion? How often is medical treatment adequate? May it ever restore the valve to actual competence? These and other questions await solution; the valve has been as yet too infrequently an object of careful study.

A growing personal experience, however, would seem to justify the following assertions:

I. In the mild or ambulant group of chronic intestinal cases, the frequency of incompetence may be distinctly in excess even of the accepted ratio of one to five.

II. When present, incompetence should be treated as an undesirable pathologic entity; an entity however usually responsive to intelligent treatment.

III. Under adequate medical treatment the patient may be assured at least some degree of improvement, with corresponding alleviation of symptoms; surgery is only secondarily indicated.

IV. Medical treatment may even restore the valve to complete competence.

V. The progress and results of treatment are under absolute control, through the agency of the bismuth-roentgen meal and enema.

Case has said, "once incompetent always incompetent." But this cannot always hold true, as witness the following case report, in which it is especially desired to focus attention upon the roentgen notes by Dr. Dodd. For though the possibility has been inferred, a moderate search of the literature has revealed no such actual proof of the restoration to complete competence by non-surgical means, of a valve previously demonstrated incompetent.

Mr. S., age 61, height 5 ft. 11 inches, weight 205 pounds. Formerly a powerful athlete, Mr. S. had become soft and heavy without losing his intellect. Since childhood he had suffered from nervous headaches induced by excitement, as I had some of those of his family. When first seen on Oct. 5, 1915, he complained of rapid exhaustion of energy, especially during the night, and of a peculiarly fitful sleeping after 3 A.M., cold limbs and feet, subnormal temperature and constant uneasiness, particularly of spells of abdominal discomfort associated

with right iliac pain and excessive gas in the intestines; the spells always were aggravated by being tired, and lasted a month or so at a time.

Examination showed fatigue posture, eyes and skin yellowish, lower lips puffy, fat pads above the clavicles, large relaxed abdomen, and moderate chronic edema of the ankles; thorax full, lungs negative; heart large but competent; abdomen flat or wind, tympanic throughout, pain and excessive peristalsis on pressure over the right iliac fossa, knee jerks very lively; all muscles of the arms very active; mentally introspective, easily depressed, pulse 70; blood pressure 165/120; are normal except for the S. p. of albumen long known to be due to a mild chronic interstitial nephritis. Roentgen examination, Oct. 7, by Dr. Dodd, showed a large transverse heart and dilated arch of the aorta, dilated cecal and colonic stasis, and an incompetent ileocecal valve.

Under treatment the posture became erect, the skin and eyes cleared, the edema of the ankles disappeared; the weight dropped 22 pounds, to 183, the puffiness under the eyes markedly decreased, as also the fat pads over the clavicles; the abdomen became inches smaller, and its muscles firm; the bowels became regular, and abdominal discomfort from gas or pain practically ceased. On April 1, Dr. Dodd reported that a "bismuth enema did not reveal any evidence of an incompetent ileocecal valve." The cardio-renal condition remained about the same, but bowel disturbances had by then been practically eliminated. Mr. S. had become fixed in his new habits of health and diet. Throughout the past summer he has remained "remarkably free from discomfort." At the end of September he had a slight recurrence of his intestinal trouble, following upon several days of physical over-exertion. He had, however, learned how to care for himself, and speedily recovered.

There are many cases of the type described. They may, without great effort, be restored to a condition of mind and body which will give promise of an enjoyable and useful old age, rather than a too early demise.

Diagnosis of ileocecal incompetence is also made by means of roentgenoscopy. In the present stage of development of the science it is as practicable to omit roentgen study of an intestinal case which does not readily react to treatment, as it is to neglect a Wassermann test in an appropriate case. Given a case with chronic intestinal history, with local pain, excessive peristalsis on pressure over the right iliac fossa, excessive gas formation not easily relieved by constipation, stasis, and evidence of excessive distension, a presumption of valvular incompetence is indicated which should be checked by roentgenoscopy. The toxic symptoms, excessive gas formation, and flat-headedness, fatigue, excessive peristalsis, and distention of the right half of the colon, the local pain, the fitful sleep, and the cold limbs and feet, the subnormal temperature, and the constant uneasiness, especially of spells of abdominal discomfort associated with right iliac pain and excessive gas in the intestines, are all symptoms which may be expected to respond to intelligent treatment. The temperature, pulse, and blood pressure, and the condition of the heart, lungs, and kidneys, should be watched, and the patient should be kept in bed, and the bowels should be kept regular by the use of the bismuth-roentgen meal and enema. The patient should be kept in bed, and the bowels should be kept regular by the use of the bismuth-roentgen meal and enema. The patient should be kept in bed, and the bowels should be kept regular by the use of the bismuth-roentgen meal and enema.

It is obvious that, for example, cold extremities and subnormal temperature may have other explanations, and in fact in the above case they were at least partly due to the mild hypothyroidism so common in stout elderly persons. But should all or most of the symptoms mentioned be present, the burden of proof that the valve is not incompetent, rests at least with the practitioner who refuses to his patient the benefit of a skilled roentgen examination.

Treatment will be considered later. Evidence has, however, been presented which suggests that treatment directed toward the relief of incompetence of the ileo-cæcal valve may be worth while, since it may result in distinct improvement in the health of the patient.

### Book Reviews.

*Pulmonary Tuberculosis.* By MAURICE FISHBERG, M.D. Philadelphia and New York: Lea and Febiger. 1916.

This volume, consisting of over 600 pages and containing many excellent diagrams, illustrations and plates, is the latest addition to the literature, already voluminous on the general subject of tuberculosis. In view of the recent comprehensive works on this subject, it is manifest that little new can be added, so that what we already know can merely be presented in new and attractive style. Dr. Fishberg states that an experience of 18 years is convincing that careful home treatment is productive of practically the same immediate and ultimate results as institutional treatment, and is less costly to the patient and to the community. The reviewer is of the opinion that the vast majority of workers in the field of tuberculosis would not agree with this statement, and that this point of view cannot possibly be maintained or proved. Dr. Fishberg very wisely calls attention to the fact, becoming of more importance every day, that not everyone infected with tuberculosis is destined to become sick, and that a sharp distinction must be made between tuberculous infection and tuberculous disease. Likewise, speaking of the value of the X-ray in diagnosis, he calls attention to a similar point that the X-ray does not necessarily give conclusive proof that the patient is sick, and in need of prolonged and costly treatment. In his chapter on percussion, he wisely states that dullness alone, without any general symptoms of phthisis, proves nothing, just as in radiography, a shadow over an apex does not prove an active tuberculous lesion. In his chapter on auscultation, the reviewer is glad to see proper value given to the whispered voice. The value of the X-ray, which many enthusiasts have considered to be very great even in the incipient stage of phthisis, Dr.

Fishberg points out to amount to very little except in the rarest of instances. In speaking of medicinal treatment, he devotes several pages to the use of creosote, ichthyol and arsenic. The reviewer is of the opinion that reference to these drugs in the treatment of pulmonary tuberculosis, except that they are of no value, whatsoever, and usually do harm, might well be omitted. With the exceptions mentioned, especially as to the value of home treatment versus treatment in a sanatorium, with which many will disagree, the book can be highly recommended. It contains an immense amount of information, representing much work clearly and attractively presented.

*Medical Hints for the Use of Medical Officers Temporarily Employed with Troops.* By J. EDWARD SQUIRE, M.D. London: Oxford University Press. 1915.

This is one of a series of war primers published by the Oxford University Press. It attempts to cover the medical problems which confront the physician of civil life who enters the army. Within the scope of 120 odd pages it is obviously impossible for the author to attempt more than a cursory survey of the medical conditions met with in active army life. The book is occasionally marred by the use of such an obsolete expression as "pleurisy is commonly caused by chill." Preventive and sanitary measures receive rather scant consideration. The book does reflect, however, the large personal experience of the author in the care of sick soldiers.

*The Basis of Symptoms, the Principles of Clinical Pathology.* By DR. RUDOLPH KREHL. Authorized translation from the Seventh German Edition. By ARTHUR FREDERIC BEIFELD. Third American edition. Philadelphia: J. B. Lippincott. 1916.

Two earlier editions of Professor Krehl's "Pathologische Physiologie" were translated by Dr. Hewlett, and are well known under the title of "Clinical Pathology."

It is somewhat hard to understand why the translator in changing the title did not adopt a literal translation, since pathological physiology represents the subject-matter of the book. This work has now reached seven editions in German and the translator has continued Dr. Hewlett's great service in making this edition available for American readers. It is not necessary to dilate with enthusiasm upon this admirable, stimulating book, even on the excuse of the appearance of a new edition. The same general outline of the previous editions is followed and the treatment is essentially the same. The translator has done his work well and occasionally helps the text by discriminating parenthetical remarks.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, OCTOBER 19, 1916

## EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief*.  
GEORGE G. SMITH, M.D., *Assistant Editor*.  
WALTER L. BURRAGE, M.D., *For the Massachusetts Medical Society*.

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States. \$6.50 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## NEW ENGLAND SURGICAL SOCIETY.

The first annual and inaugural meeting of the New England Surgical Society was held in Boston on October 5, 6, and 7, under the presidency of Dr. Samuel J. Mixer of this city. The sessions were held at the Harvard Medical School, at the various Boston hospitals, at the Harvard Club and at the Copley-Plaza Hotel.

At the initial meeting at the Harvard Medical School on the morning of October 5, there were papers by Dr. John W. Churchman of New Haven, Conn., on "A Group of Injuries in Modern Warfare," and by Dr. Edward P. Richardson of Boston on "Jejunum After Following Posterior Gastro-entostomy." There was a symposium on the large intestine, with papers by Dr. Homer Gage and Dr. Ernest L. Hunt of Worcester, Dr. Peer P. Johnson of Beverly, Dr. John W. Keefe of Providence and Dr. Frank H. Lahey of Boston. There were demonstrations and operative clinics at the

Children's Hospital, Free Hospital for Women, Massachusetts General Hospital, Carney Hospital, Peter Bent Brigham Hospital, and the Boston City Hospital. On Friday afternoon there was a second literary session at the Harvard Medical School and in the evening a dinner at the Harvard Club, at which the presidential address was delivered. The complete proceedings of the New England Surgical Society will be published in later issues of the JOURNAL, which is its official organ.

The New England Surgical Society was organized early in 1916, with a membership of 75 representative surgeons from the six New England states. It comprises a group from Portland, Maine, representing the Bowdoin Medical School; a group from Burlington, Vt., representing the University of Vermont; a group representing the Dartmouth Medical School, a group from Providence, R. I.; a group from the Yale Medical School and other surgical centers in Connecticut; and a large group from Massachusetts. During its initial year the officers of the Society have been as follows: President, Dr. Samuel J. Mixer of Boston; Vice-president, Dr. John B. Wheeler of Burlington, Vt.; secretary and treasurer, Dr. Philenon E. Truesdale of Fall River, Mass. The executive committee has consisted of Dr. John W. Keefe of Providence, R. I.; Dr. Joseph M. Flint of New Haven, Conn.; Dr. Lyman Allen of Burlington, Vt.; Dr. Herbert L. Smith, Nashua, N. H.; and Dr. William L. Cousins of Portland, Me.

The Society will meet but once a year, in the leading New England cities successively, and at each annual meeting will make a special effort to obtain from its members their most recent and best productions. The arrangements for this first meeting in Boston were under the able management of a committee consisting of Dr. William P. Graves, Dr. Charles A. Porter, Dr. Fred B. Lund, Dr. John T. Bottonby, Dr. David Cheever, and Dr. Charles G. Mixer. Upon the occasion of this meeting, which was well attended and met with a notable degree of success, the JOURNAL takes pleasure in extending its cordial good wishes to the New England Surgical Society, whose activities should lead not only to the production of valuable scientific material in surgery, but to the closer cooperation and mutual acquaintance of practitioners in surgery in the large hospital centers throughout New England.

## ELIMINATION OF THE RAT.

IN the issue of the JOURNAL for September 21, 1916 (Vol. clxxv, p. 397), we published, with editorial comment in another column, an important paper by Dr. Mark W. Richardson of Boston, formerly secretary of the Massachusetts State Board of Health, advancing the theory of the transmission of poliomyelitis through the agency of the rat flea. Immediately following the publication of this article, a movement was initiated by the Women's Municipal League of Boston for the extensive destruction of rats in this city. This movement was originated by Mrs. Robert S. Bradley, and will be carried out under the management of Mrs. Albert T. Leath-erbee. Circulars and posters have already been issued, and the following statement of its purposes has been made by the League:

"Aside from its menace as a pathological agency, the economic loss due to rats is enormous. This creature is omnivorous and otherwise destructive, and there is no known commodity of manufacture and commerce that it does not injure. Government experts have officially proclaimed that rats consume property to the extent of \$1.82 each per year, and that their number equals the human population. The rat is a menace to buildings in its liability to gnaw out supports and foundations, unless thoroughly rat-proofed, and in its ability to cause fires through gnawing of matches and the insulation from electric wires—which last item is computed to cost the underwriters about \$15,000,000 yearly. The Women's Municipal League intends to go about this matter in a perfectly practical manner along lines already proved effective. It will form rat clubs, which will work in co-operation through the entire city, which clubs will be instructed by competent rat catchers in the most desirable and effective methods of rat extermination. In this work they have the hearty support of the Mayor and the City Administration, and the endorsement and official co-operation of the City Board of Health. To prosecute properly this undertaking, it will be necessary to raise funds from public subscription, but as rats are destroying nearly one and one-half million dollars of property yearly in the city, the League feels that the people should be glad to subscribe a few thousands on this work, realizing that every rat killed means the extinction of its progeny, which are to be figured in the hundreds yearly. While they hope that it may be possible with time, the enactment of proper ordinances and the general education of the people as to the true habits of rats, to make the city ratless, they know that much can be done now in exterminating large numbers. If San Francisco could in a few months destroy over 500,000, surely Boston can

do as well. They hope for the generous support of the citizens."

Whether or not Dr. Richardson's theory is proved correct, that poliomyelitis is transmitted through the agency of the rat flea, it is well recognized by physicians that the rat, from many aspects, is an important menace to the health welfare of the community. The Women's Municipal League, therefore, deserves and will receive the cordial commendation and support of physicians in its efforts towards the elimination of the rat for the benefit of the public.

---

 COLORED THINKING.

WE all have ways peculiar to ourselves of visualizing abstract conceptions. Sometimes these are due to aids to memory which we used in learning such educational elementaries as the alphabet, the multiplication table, the months of the year, etc., or they may be due to certain fortuitous associations. Thus the particular color a letter was painted in the picture book studied by a child may determine his chromatic conception of that letter through life. Or the object used to illustrate each letter may be associated in the same way: A, with apple; B, with banana; C, with cherry and so on. We know a physician who thinks of the numbers one to twenty as a sort of ladder; after twenty there is an abrupt descent and the numbers climb again to thirty, which is a little higher than twenty; this process is repeated with each set of ten and when 100 is reached this is thought of as several small hills close together. A thousand is represented by a large orchard and a million is just something very bright, but has no more definite appearance.

Probably the commonest way of representing abstract ideas is by color—indeed, it is doubtful whether any of us is entirely without a little of this chromatic thinking. In some individuals it is so pronounced that each numeral has its distinctive color. Sounds, tastes, and emotional affects all have their chromatic representation to such persons. In a recent paper Professor Blanchard<sup>1</sup> proposes for this psychic phenomenon the term "chromatic encephalopsy." We have been accustomed to refer to it merely as "thinking in color." It is as yet a question whether or not there are any other psychic peculiarities associated with it. Dr. Fraser Harris,<sup>2</sup> writing in 1908, states that these peo-

pie, whom he calls, after Galton, "psychochromæstheses" or merely "seers," are "as a rule rather above than below the intellectual average." According to Havelock Ellis,<sup>4</sup> women have this faculty more frequently than men.

The chief characteristics of chromatic conception were laid down by Sir Francis Galton in 1883, and have been in the main confirmed by other observers. They are as follows: First, these associations between concepts and colors have been formed at a very early age. Second, these concepts are distinctly individual; thus the letter "S" may be white to one person, green to another, blue to another, and so on. Only by coincidence, as it were, do two persons have the same psychogram. Third, these conceptions are definite and change very little in the course of time. Such changes as occur are not very radical either, that is, white may change to silver and silver to gray, but never white to black. Fourth, this mental faculty is hereditary, as much so as Huntington's chorea.

It is impossible to tell the exact personnel of the distinguished company in which the psychochromæsthete finds himself, for it seems difficult to get persons to admit this form of thinking, probably on account of an impression that it is a childish sort of thing. However, we know that the following persons may be listed as being "seers": Sir Francis Galton, the scientist; Ellen Thornycroft Fowler, the author; Dr. Head, the neurologist, the Rev. S. Henslow, the botanist, and Baudelaire, the French poet. These are undoubtedly only a few of the eminent persons thus endowed, but as time goes on and more is learned about this faculty, it is possible that some of its implications will be so creditable that we shall find persons boasting of it instead of concealing it, as is often the case now.

case of Australia, as evidenced by the "Health Act Amendment Act," which has recently become a law by receiving the Royal approval. It is directed against venereal disease, and is extremely drastic in its provisions. It provides that no one except a doctor shall attend such cases, penalty \$250; a person knowing or suspecting that he has such a disease shall put himself under medical treatment, penalty \$100; physicians must report such cases, penalty \$25; they must also report failure of the patient to attend for six weeks, give written warning to the patient of the danger of the disease, with special cautions against marrying, penalty of non-observance of each of these rules, \$25; parents of children under sixteen must answer for them, penalty, \$50. Furthermore, should the Commissioners of Public Health receive the information that any one is suffering from venereal disease he must require that person to furnish a certificate from a physician that it is, or is not, true; if for any reason he feels dissatisfied with this certificate he may require a health officer or two private doctors to examine the suspect. The health commissioner is also authorized to arrest and detain any person suffering from venereal disease for two weeks if he thinks that there is danger of infection, and any person knowingly infecting another is fined \$250.

Provision is made that all proceedings under this act shall be secret, and any newspaper publishing an account of such proceedings shall be fined \$500 for the first offence, \$2500 for the second. The law, furthermore, forbids advertising of medicine, instruments, or appliances for venereal disease, impotence, female irregularities, etc. No printed matter in regard to such devices is allowed to be distributed in any way. Any breach of confidence by an administrator of the act may be punished by a fine of \$500.

To aid in educating the public in this matter, the government has issued a pamphlet dealing with sexual matters. This is written in a plain, non-technical style, the important passages are printed in red ink, and the common names of organs and diseases are used, besides their scientific ones, in order that there may be no misunderstandings. The ways in which these diseases may be contracted, the danger of infecting others, the horrible physical effects possible, and the precautions to be taken are all described clearly and for a full understanding of the importance of skillful treatment, and the fact that

## THE REGULATION OF VENEREAL DISEASE IN AUSTRALIA.

THE Western Hemisphere seems determined to be more progressive than the Eastern, even if a colony has to display its progressiveness at the expense of its mother country. Such is the

hint of the treatment is given—quite properly. Some of the most prevalent fallacies about sexual matters are mentioned and dispelled. This book must be handed by every physician to his venereal patients and it is also distributed in other ways, notably to the soldiers in camp.

This campaign against venereal diseases has the merit of enthusiasm, justice and vigor. The act in question is, perhaps, a little too rigorous in parts and in other parts leaves some loophole for evasion, but time will round off the rough edges. We hope that the Australian people will be ready for this legislation; otherwise, of course, it will soon become a dead-letter. The spirit in which it was conceived, however, is admirable, and coming generations will reap the benefit.

### A NEW FORM OF POST-GRADUATE TEACHING.

THE Springfield Academy of Medicine, under the presidency of Dr. H. W. Van Allen, has organized a new form of post-graduate teaching which bids fair to be most successful, and seems to possess many advantages. The academy announces the following courses, arranged with the coöperation of the Harvard Graduate School of Medicine, to be given in Springfield by teachers from the Harvard Medical School.

Eye, Ear, Nose and Throat. Philip Hammond, E. A. Crockett, Harris P. Mosher, Alexander Quackenboss. Tuesdays from Nov. 14 to Dec. 19.

Dietetics and Gastroenterology. Franklin W. White. Sundays from Nov. 17 to Dec. 22.

Clinical Laboratory Diagnosis. Lesley H. Spooner. Tuesdays from Jan. 2, to Feb. 6.

Obstetrics and Gynecology. Franklin S. Newell, William P. Graves. Fridays from Jan. 5, to Feb. 9.

Dental Infections and Arthritides. Geo. H. Wright, E. G. Brackett. Tuesdays from Feb. 13, to Mar. 20.

Cardio Vascular-Renal & Pulmonary Diseases. Frederiek T. Lord. Fridays from Feb. 19 to Mar. 23.

There are about six exercises in each course, beginning at 4:15 in the afternoon and lasting two hours. The number of physicians taking the different courses is to be limited by each instructor, and the courses are open to all members of the academy upon payment of a registration fee of five dollars. For each set of exer-

cises there is to be a monitor, selected from the local physicians, whose duty it is to see that all the material required by the instructor is made ready for him. Already in Springfield the success of the plan is assured and the courses are nearly all full. Provided the equipment and the variety of illustrative cases can be made comparable to those in the university centre, there can be no question of the advantages which such a course possesses for the busy physician practicing at a distance from the centre. For the instructor it means only the extra time of the train journeys, and limits this inconvenience to one person instead of inflicting it upon many.

It is obvious that certain courses can not well be given away from the technical laboratories of the medical schools or the wards of great hospitals, but the JOURNAL believes that this plan offers very great opportunity for much extension of knowledge and for an interchange of ideas, valuable alike to the university and to those whose practice is at a distance from the usual teaching centres. If the plan is continued, and is extended to other communities in New England, it may go far toward welding together medically this important northeastern corner of the country. It will bring the men doing work under the somewhat self-centering influence of large hospitals and special opportunities into contact with the broader problems of medical practice away from the university, and will increase their respect for their fellow workers. It will also prove to men outside that what may seem to them the self-satisfaction of the university men is often only a self absorption which needs the reagent of contact to make evident the presence of a real desire for coöperation.

### MEDICAL NOTES.

**POLIOMYELITIS EPIDEMICS.**—On Friday, October 13, the total number of cases of poliomyelitis in New York City reached the amount of 9187, with 2352 deaths. In Massachusetts the number of cases during the first fortnight of October reached a total of 331. The total number of cases in this Commonwealth since January first is 1347, of which 337, with 68 deaths, have been in Boston. There have been 23 cases, without fatality, at Worcester, Mass., and 85 cases in Providence, R. I.

**PREVALENCE OF DISEASE IN THE UNITED STATES.**—The weekly report of the United States Public Health Service for September 29 states that during the month of August, 1916,

there were in Mississippi, 33,579 cases of malaria, 658 of pellagra, and 1040 of typhoid fever. During the same period there were 419 cases of malaria in Louisiana and 940 cases of typhoid fever in Indiana.

**THE ORIGIN OF INTESTINAL ANASTOMOSIS.**—A correspondent in the issue of the *Lancet* for September 23, 1916, draws attention to the mediæval origin of intestinal anastomosis. He points out that Lanfranc, in his "Science of Chirurgie" (Capt. 7, Treatise 2), describes suture of the severed intestine over a pipe of elder. Lanfranc was the pupil of Salicrampi of Bologna, to whom, if not to Lanfranc, the origin of the idea may be due. This use of the elder pipe, dating back to 1250 A.D., may be regarded as the precursor of the Murphy button.

**HOSPITAL GIFT.**—It is announced that Mr. Herbert Kaufman, of Pittsburgh, Pa., has given, through Dr. H. B. Frauenthal, the sum of \$1,000,000 to the New York Hospital for Deformities and Joint Diseases, to be used for the erection of a new building and as an endowment fund.

#### EUROPEAN WAR NOTES.

**TUBERCULOSIS IN BELGIUM AND FRANCE.**—Dr. William Palmer Lucas, formerly instructor in pediatrics at the Harvard Medical School, later professor of pediatrics at the University of California, who had been engaged by the American Belgian Relief Commission to study health conditions in the conquered portion of that country, has recently made, under date of August 14, a report of his findings, which is, in part, as follows:

"It may be said at once that the increase in tuberculosis appears to me to be mainly a result of lowered vitality due to under-feeding, and that, if conditions were now to return to the normal, the unaffected adults would, upon liberal nourishment, within two or three months probably return to their former health conditions. This, of course, is not true of those who have become affected with tuberculosis, nor is it so true of the adolescent children, who are probably suffering more than any other group in this class.

"During the coming winter, with a diminution in the native supply of vegetables and fruit, which now, to a certain extent, these classes are able to procure, the ration will be considerably lower than it is at the present time, and unless something can be introduced, especially for the tuberculous, the whole tuberculosis situation will undoubtedly progress more rapidly than it has done in the past.

"Every tuberculosis sanatorium in Belgium is crowded, the waiting lists of all the sanatoria have increased, and the waiting cases are more acute than formerly.

"Not every aspect of the health conditions of the children in Belgium is so gloomy as these facts would indicate. Infant mortality has fallen since the beginning of the war and deserves special comment. It is generally evident that infant conditions are better than normal, this class having been the object of great solicitude since the beginning of the war.

"The solicitude of the whole relief organization over the question of health and nutrition has been insistent since its inception. The maintenance of these measures is an absolute and daily necessity to the population. The interruption for a single month of the work that is now being accomplished by the relief organization would unquestionably bring a physical debacle to the industrial and lower commercial classes."

In this conjunction may be noted the work already undertaken in behalf of tuberculous French soldiers, of whom it is reported by Mrs. Edith Wharton, that there are at least 100,000. In behalf of the French Tuberculous War Victims Committee, Mrs. Wharton has recently made the following report and appeal:

"It is urgently needful to provide further assistance without delay, and American initiative, by acting rapidly and efficiently, may not only render an immediate service, but set an example that will be followed in time by other organizations of the same kind.

"The work projected by the Tuberculous War Victims Committee is as follows:

"1. To establish as soon as possible at least three sanitary stations of about eighty beds each in different climates suited to different forms and stages of the disease.

"2. To open a hospital of about fifty beds in Paris, in which the patients may be kept under observation until it is decided to which station they should be sent.

"3. A separate station, for women and children, or a separate colony for women and children at each station, will form a complementary part of the work. At the present moment no free hospital for tuberculous civilians is open in France, and all existing hospitals for civilian patients are overcrowded and in a state of disrepair. Large numbers of the women and children from the invaded provinces are held ready to succumb to the shock and privations of travel, and are gone, and incipient cases of tuberculosis of alarming frequency in the provinces.

"4. The object of the committee will be not only to restore the curative value of the climate, but, so far as possible, to teach the children and adults, by enabling them to earn a few francs a day, or at least a few francs a week. With this view, a number of the children will be placed at its disposal, and the station will be surrounded by a few small plots of land, to be used as a kind of school garden, to which all sorts of vegetables will be sent.

"5. It is the intention of the committee to keep each patient as long as his or her condition requires.

"6. The Tuberculous War Victims Committee will be administered by Americans, but the superintendence and management of the sanitary stations will be principally in the hands of French doctors, superintendents and nurses especially qualified for the care of the tuberculous.

"The Boston committee, which is coöperating with Mrs. Wharton, contains the following-named persons:

"Miss Sally Fairchild (chairman), Dr. Vincent Y. Bowditch, Mrs. Arthur Cabot, Miss F. G. Curtis, Mrs. Allan Forbes, Mrs. Richard W. Hale, Dr. Edwin A. Locke, Mrs. George Cabot Lodge, Mrs. Robert W. Lovett, Miss Ellen Mason, Miss Fanny P. Mason, Mrs. Roger B. Merriam, Mrs. Edward Pickman, Professor W. T. Sedgwick and Dr. F. C. Shattuck.

"Richard W. Hale, 16 Central Street, Boston, is treasurer of the committee, and funds are earnestly solicited for the work. All subscriptions will be duly acknowledged in the public press."

**WAR RELIEF FUNDS.**—On Oct. 14 the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund .....	\$157,510.74
French Wounded Fund .....	126,240.71
Serbian Fund .....	102,886.07
Syrian Fund .....	67,646.61
Surgical Dressings Fund ....	48,425.45
Polish Fund .....	45,779.83
Italian Fund .....	25,968.54
St. George's Fund .....	14,731.92
French Tuberculous Fund ...	3,001.00
Louvain Professors' Fund ....	605.00

#### MEXICAN NOTES.

**MORBIDITY AND MORTALITY OF TROOPS.**—Report from Washington on October 4 states that during the week ended September 30, the morbidity percentage among militia troops on the Mexican border was 2.25, with seven deaths, as against 2.38 and six deaths for the preceding week. The corresponding figures for regular troops during the same period were 3.42, with five deaths, as compared with 2.53 and seven deaths for the previous week.

#### BOSTON AND NEW ENGLAND.

**WEEK'S DEATH RATE IN BOSTON.**—During the week ending Oct. 14, 1916, the number of deaths reported was 218, against 226 for the same period last year, with a rate of 14.95, against 15.21 last year. There were 34 deaths under one year of age, against 39 last year; and 65 deaths over 60 years of age, against 55 last year.

The number of cases of principal reportable diseases were: diphtheria, 33; scarlet fever, 18; measles, 8; whooping cough, 9; typhoid fever, 3; tuberculosis, 48.

Included in the above were the following cases of non-residents: diphtheria, 6; tuberculosis, 8; typhoid fever, 1; scarlet fever, 1; measles, 1.

Total deaths from these diseases were: diphtheria, 1; measles, 1; whooping cough, 1; tuberculosis, 20.

Included in the above were the following deaths of non-residents: tuberculosis, 4.

**BOSTON BABY HYGIENE ASSOCIATION.**—The Boston Baby Hygiene Association has recently issued statistics of its work for the past summer.

"During June, July, August and September, 3258 babies were cared for. These babies made 11,419 visits to medical conferences, an average conference attendance of forty, and received from the nurses 21,084 home visits. The registration showed an increase over the corresponding months last year of 8%. Conference attendance increased 24% and nurses' visits 26%, the increase in service being three times the increase in registration. As would be expected, although the number of babies cared for was greater than last year, fewer babies were referred to physicians and hospitals on account of illness. The Association at present has thirteen stations, seventeen medical conferences each week and seventeen full-time nurses."

Funds are urgently needed for the continuance of the work during the coming winter, and contributions for this purpose should be sent to the treasurer, F. Abbot Goodhue, Esq., 296 Boylston Street, Boston.

**OPENING OF NORWOOD HOSPITAL.**—The new Norwood (Mass.) Hospital was formally opened to the public for inspection on October 5. It will accommodate thirty patients and has a nursery and seven private rooms. The ground floor is devoted to the men's ward and to administrative offices; the second floor, to the women's ward, operating room and private rooms; and the third floor to the maternity department. The former building of the Hospital is to be moved and converted into a nurses' home.

**HOSPITAL BEQUESTS.**—The will of the late Mrs. Thomas Mack, recently filed in the Suffolk Court, contains a bequest of \$3000 to the New England Hospital for Women and Children.

The will of the late Ellen Williams contains a bequest of \$300 to the Holy Ghost Hospital.

The will of the late Henry F. Lynde, of Somerville, Mass., who died on September 24, contains bequests of \$3000 each to the American Red Cross, the Boston Dispensary, and the Massachusetts General Hospital.

The will of the late Margaret A. Simpson of Somerville, Mass., who died on September 9,

contains a bequest of \$15,000 to the Somerville Hospital, of which \$5000 is for a free bed and \$10,000 to constitute a trust fund, the income of which is to be used for the general purposes of the institution.

## Massachusetts Medical Society.

### STATED MEETING OF THE COUNCIL.

A STATED meeting of the Council was held in John Ware Hall, Boston Medical Library, Wednesday, October 4, 1916, at 12 o'clock, noon. The president, Dr. Samuel B. Woodward, was in the chair, and the following 93 councilors present:

BARNSTABLE,  
E. E. Hawes.  
C. W. Milliken.

BRISTOL NORTH,  
W. H. Allen.  
R. D. Dean.  
F. A. Hubbard.

BRISTOL SOUTH,  
E. F. Curry.  
W. A. Dolan.

ESSEX NORTH,  
L. J. Clarke.  
G. E. Kurth.  
E. H. Noyes.  
J. J. O'Sullivan.  
F. W. Snow.

ESSEX SOUTH,  
Emile Poirier.  
C. H. Bangs.  
R. E. Bicknell.  
N. P. Breed.  
J. F. Donaldson.  
P. P. Johnson.  
W. G. Phippen.

FRANKLIN,  
G. P. Twitchell.

HAMPDEN,  
E. P. Bagge, Jr.  
M. P. Birnie.  
T. S. Bacon.  
E. A. Knowlton.

HAMPSHIRE,  
J. S. Hitchcock.

MIDDLESEX EAST,  
C. J. Allen.  
G. N. P. Mead.

MIDDLESEX NORTH,  
J. V. Meigs.  
J. A. Gaze.

MIDDLESEX SOUTH,  
M. H. Bailey.  
H. T. Baldwin.  
C. H. Cook.  
G. W. Gay.  
A. A. Jackson.

G. A. Miles.  
C. E. Mongan.  
J. F. O'Brien.  
W. A. Putnam.  
Godfrey Ryder.  
E. H. Stevens.  
F. W. Taylor.  
J. O. Tilton.  
Julius Tolman.  
G. W. W. Whiting.  
Alfred Worcester.

#### NORFOLK.

T. F. Greene.  
E. B. Brigham.  
A. N. Broughton.  
P. W. Carr.  
C. B. Faunce.  
R. W. Hastings.  
G. W. Kaan.  
Bradford Kent.  
Joseph Kittredge.  
W. A. Lane.  
T. J. Murphy.  
A. P. Perry.  
J. W. Pratt.  
Victor Safford.

#### NORFOLK SOUTH.

C. S. Adams.  
J. C. Fraser.  
E. N. Mayberry.

#### PLYMOUTH.

A. A. McKeen.  
Gilman Osgood.  
F. G. Wheatley.

#### SUFFOLK.

E. S. Boland.  
E. M. Buckingham.  
W. L. Burrage.  
David Cheever.  
J. A. Cozart.  
G. A. Craigin.  
E. G. Cutler.  
R. L. DeNormandie.  
Albert Ehrenfried.  
J. B. Hawes, 2d.  
H. T. Hutchins.  
J. L. Morse.  
Abner Post.  
Anna G. Richardson.

G. B. Shattuck.  
H. F. Vickery.  
Dr. H. Walker.  
C. F. Withington.  
David Harrower.  
A. G. Hurd.  
F. H. Washburn.  
S. B. Woodward.  
C. D. Wheeler.

#### WORCESTER.

G. O. Ward.  
F. H. Baker.  
Homer Gage.  
WORCESTER NORTH,  
E. L. Fiske.  
A. P. Mason.

It was voted to dispense with the reading of the records of the last meeting.

The president said he appreciated the honor of election to the presidency, and bespoke the cooperation of the councilors in the furtherance especially of desirable legislation affecting the medical profession; that physicians were too apt to underestimate the influence that a united profession could exert at the State House—a power that is recognized by the layman. He thought that the proposed consolidation of the Boards of Registration last year was defeated partly because of letters of protest that were sent to every senator and representative by a district medical society. The Committee on State and National Legislation has done notable work at the State House for many years. It has an auxiliary committee composed of one or more members from each senatorial district. It seems to be desirable that the members of this auxiliary committee should keep in touch with the family physicians of the legislators in order that they may be informed through the central committee of the facts regarding proposed legislation from a medical point of view. Prompt cooperation by the district secretaries with the Committee on State and National Legislation was requested by the president as chairman, under the by-laws, of this committee.

The committee, consisting of the president, secretary, treasurer and the chairman of the standing committees on membership and finance and public health, elected at the annual meeting, June 8, 1915, had conferred with Henry Copple Greene, Carl Carstens and Miss Mary Beard, as authorized, and last June decided to engage Mr. E. A. Ingham, of the department of biology of the Massachusetts Institute of Technology and a graduate of the school of public health at Harvard Medical School as an agent of the committee, and is now at work under the direction of the Committee on Public Health. The funds subscribed to the public health individuals, amounting to some \$100,000, are now in the hands of the treasurer, and will be expended by the agent through the action of the above committee. The committee has the following objects:

1. To stimulate the interest of the medical profession in Massachusetts in the study of hygiene and preventive medicine.
2. To urge on the State the importance of public health officers.
3. To stimulate better methods of inspection of schools, infants, and children.

work, district nursing, anti-tuberculosis work, industrial hygiene, sanitary engineering, and the prevention of the common communicable diseases.

4. To investigate the health conditions of the State, with reference to the public health work.

During the summer the president had enjoyed the hospitality of five of the District Societies at their regular meetings, and had taken pleasure and profit in this close association. He hoped that the councilors were ready for co-operative work for the good of the Society, "one for all and all for one."

The president nominated and the Council appointed these delegates to the annual meeting of the Vermont State Medical Society, at St. Johnsbury, October 12-13, 1916: F. C. Downing, Lanesborough; N. P. Wood, Northfield.

In the same manner were appointed this committee to audit the treasurer's accounts: E. O. Otis, Boston; J. B. Ayer, Boston.

The following report of the Committee on Membership and Finance on membership and the report on finance were presented by Dr. Alfred Worcester, in the absence of the chairman. Both reports were accepted and their recommendations adopted by unanimous votes:

#### REPORT ON MEMBERSHIP.

THE COMMITTEE ON MEMBERSHIP AND FINANCE makes the following recommendations as to membership:

1. That the following named Fellows be allowed to retire, under the provisions of Chapter I, Section 3, of the by-laws:

John Gilbert, of Fall River.  
William Henry Grainger, of East Boston.  
William LeRoy Paddock, of Pittsfield.  
Frank Edward Porter, of Auburndale.

2. That the following named Fellows be allowed to resign, under the provisions of Chapter I, Section 7, of the by-laws:

Clarence Pennell Baxter, of Topsfield.  
Charles Frederick Morse, U. S. A. ("Somewhere in Mexico").

3. That the following named Fellows be deprived of the privileges of fellowship for non-payment of dues, under the provisions of Chapter I, Section 8, of the by-laws:

Anna Judkins Andrews, of Boston.  
Osmyn Baker, of unknown address.  
Willmar Howard Bliss, of Strewsbury.  
William Frederick Boos, of Brookline.  
Nathaniel Perkins Breed, of Douglaston, Long Island, New York.  
Chester Perkins Brown, of Cambridge.  
Christopher James Carr, of Saxonville.  
George Alanson Crittenden, of Huntington.  
Richard Andrew Elliott, of Avon.  
Jay Percy Graham, of Springfield.  
Harry John Hagerty, of Worcester.  
William Frank Hayward, of East Brookfield.  
Clyde Clifford Johnston, of Springfield.  
Patrick Joseph Kingsley, of Dorchester.  
Antoinette Frederic Konikow-Bucholz, of Malden.  
Myron Lawrence Marr, of Dorchester.  
James Zuslofsky Naurison, of Springfield.  
Walter Erie Lothar Nietsch, of New Bedford.  
William Nelson Noyes, of Salem.  
John Wilson Parks, of East Boston.  
Laurence Earl Poole, of Gardner.

John Thomas Haliburton Powers, of Chicopee Falls.  
Julia Seton Sears, of unknown address.  
Thomas Ahern Shaughnessy, of Leominster.  
Eleanor Mary Slater, of Denton, Texas.  
Caroline Louise Thomas, of Malden.  
Thomas Henry Tracy, of unknown address.  
Frederick Myles Turnbull, of Allston.  
John William Voss, of Beverly.  
Harold Lowe Wallace, of Allston.  
Edward Silvanus Ward, of North Attleborough.  
Alva Harding Warren, of Everett.

4. That the following named Fellows be allowed to change their district membership, without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

Donald Vinton Baker, from Middlesex South to Suffolk.  
Eugene Gorham Hoitt, from Norfolk to Middlesex South.

For the Committee on Membership and Finance,  
CHARLES M. GREEN, *Chairman*.  
REPORT ON FINANCE.

THE COMMITTEE ON MEMBERSHIP AND FINANCE makes the following recommendation as to Finance:

That the affiliation with the BOSTON MEDICAL AND SURGICAL JOURNAL be continued, at an expense to the Society of three dollars (\$3.00), for each member in good standing.

For the Committee on Membership and Finance,  
CHARLES M. GREEN, *Chairman*.

The secretary read the reports of committees appointed at the last meeting to consider the petitions for reinstatement of J. D. Taylor, E. J. McCarthy and C. A. Oak, and the Council acted favorably on all of them. The petition of P. S. Marie was referred, by vote, to this committee: F. A. Hubbard, W. Y. Fox, A. F. Milot.

An invitation from the National Association for the Study and Prevention of Tuberculosis to send delegates to the third New England Tuberculosis Conference at New Haven, Conn., was read. It was moved and seconded that delegates be sent, and being put to a vote, was so voted, and these delegates were appointed on nomination by the president: A. K. Stone, Boston; A. C. Getchell, Worcester; G. F. Hart, Webster.

The president nominated and the Council appointed Homer Gage, Worcester, chairman, and J. B. Howland, Boston, secretary of the Section of Hospital Administration that was established by vote of the Council last June.

Dr. E. E. Hawes read a petition from the Barnstable District Medical Society asking that the annual dinner and reunion of the Society be held at 1 p.m., as in former years. He explained that the Fellows in his district, in order to attend the annual dinner, were forced to spend two nights in Boston; that they especially missed the social features of the meeting; that if Barnstable was the only district thus affected it would withdraw its petition; that it was his opinion that the dinner had not been so well attended since the change had been made, and he would like to have the matter discussed. Dr. Broughton, who was chairman of the Committee of Arrangements when the change was made in 1912, pointed out that the first evening dinner was attended by 940, as against a previous at-

tendance at midday dinners of about 1200. At the next dinner there were 1198 diners. When the plan of having every Fellow who attended the dinner pay \$1 was introduced in 1914, the attendance fell to about 700 and had remained there since. (1914, 700; 1915, 763; 1916, 704.) He thought that the previous one o'clock dinners had been undignified, and that many of the diners left immediately after the dinner, without waiting to hear the speakers, and that the character of the banquets had been improved by the change.

Dr. Withington regretted that the Fellows in the Barnstable and Berkshire districts were so far away that it was difficult for them to attend without spending another night, but he thought that there were so many living within forty miles who were able to attend an evening dinner, that that was the better time for a banquet. He suggested that the dinner might be given on the first day of the annual meeting, Tuesday, in the evening, rather than on Wednesday evening, and that the Committee of Arrangements might be able to arrange for it at that time. He made a motion that the time of the annual dinner be referred to the Committee of Arrangements, with a request to report to the Council at its February meeting, and it was so voted.

Dr. J. B. Blake made the following report for the delegation to the House of Delegates of the American Medical Association, last June:

**REPORT OF DELEGATES FROM THE MASSACHUSETTS MEDICAL SOCIETY TO THE HOUSE OF DELEGATES, AMERICAN MEDICAL ASSOCIATION.**

Massachusetts was represented by a complete delegation at the June meeting of the American Medical Association in Detroit.—J. B. Blake, P. B. Lund, G. Osgood, H. G. Stetson, L. F. Woodward.

An unusually large amount of work was accomplished by the House of Delegates with an exceptional unanimity of action; important changes were made in methods of procedure, and extremely interesting reports received, considered and adopted. A summary of the proceedings appeared in an editorial in the *American Medical Association Journal* of June 24th—which gives a good idea of the results.

"The Detroit session promises to be the most epoch-making of any since 1901 for two reasons: First, and more important, was the creation of the office of Chairman of the House of Delegates. This will relieve the President of the Association of the task of presiding over the House of Delegates. The President is usually elected on account of his scientific attainments, and not because of his ability to preside over a deliberative body. This new order of things will be a great relief to the President, and will give him time to attend to and participate in the functions which naturally appeal to the presiding officer of a great scientific body such as the Scientific Assembly has become. On the other hand, the House of Delegates will be presided over by a man selected because of his knowledge of the activities of the Association, of the procedure of the House of Delegates, and on account of his ability as a presiding officer. The House selected as its first Chairman, Dr. Hubert Work of Pueblo, who for many years was a member of the House and who is thoroughly conversant with its procedures. The second epoch-making change is that which provides that the opening meeting of the

Scientific Assembly—the General Meeting—shall be held on Tuesday evening, the scientific sections to convene on Wednesday morning instead of on Tuesday afternoon as heretofore. The main object of this change is to give the House of Delegates two days for its deliberations before the opening of the Scientific Assembly. It is unnecessary to dilate on the importance of this change so far as the House of Delegates is concerned; many men have hesitated to serve as members of the House because that work has prevented them from attending the sections. Under the new order of things the great probability is that the House of Delegates will complete its work on Tuesday, except for the election of officers, and business incidental to its closing meeting. The change will also be of decided advantage to the Scientific Assembly. Heretofore the Scientific Assembly commenced Tuesday morning, the first half day being taken up with the opening general meeting. Hereafter the opening exercises will take place on Tuesday evening, and the scientific sections will begin their programs on Wednesday, continuing through Thursday and Friday, meeting both morning and afternoon."

Among the other matters that came before the House was the consideration of the National Board of Medical Examiners. Dr. Rodman, the former President of the American Medical Association, was very active in originating and working for the establishment of this Board. There are great possibilities which may be expected from the activities of this Board in the matter of standardizing the licensing of physicians in the different states throughout the country, and it is, therefore, of vital general interest. The Board has sought the endorsement of the great national societies; after a very careful and rigorous investigation the House of Delegates gave its cordial endorsement to the National Board of Medical Examiners. A Massachusetts physician is a member of this Board.

The Massachusetts delegates were faithful in attendance and willing in the work of the meetings. The entire New England delegation agreed to nominate, for the Board of Trustees, Dr. Everett Jones McKnight, of Hartford, Connecticut, to take the place of Dr. Lutz, of St. Louis, who had died, and Dr. McKnight was elected. Massachusetts physicians prominently represented in all the important committees and committees of the American Medical Association.

Dr. L. M. Paley made an oral report of his attendance as a delegate at the 150th anniversary of the New Jersey Medical Society, June 20, 1916, at Ashbury Park, New Jersey. The most cordially received and interesting of the kindly messages were sent by the Massachusetts Medical Society. He thought well of the custom of that society, namely, to write the wives, mothers and sisters of the members to their anniversary and to the Massachusetts Medical Society.

The privileges of the new hospital of the R. B. Greenough Hospital, Boston, were commending Senator Worcester, of the Olney for their services in the history of the Army Reserve, and the amendment which would give the history of the Army Reserve, and the Guard are still a part of the medical officer, and the proper to be of the Army and the proper to be of the Army. After discussion by Dr. Deane, Dr. W.

and Dr. Stevens, the resolution was laid on the table.

Dr. F. J. Cotton presented the following report for the Committee on Industrial Health Insurance:

Your committee was entrusted with the care of medical interests in the face of impending legislation to provide workmen's sickness insurance as a compulsory state insurance measure. We say "impending," for though it seems rather unlikely that such a measure will be passed at the next session of the Legislature, yet it seems to be coming pretty certainly before very long. It seems to be so imminent that we should be ready for it. What we did first was to talk over the general medical question, and then to take up the work done by the committee of the American Medical Association presented last spring. This report, published in the *JOURNAL* of the Association June 17, 1916, is probably well known to many of you. After very careful consideration in detail, your committee found only minor points in which we differed or wished to add to this report. Our comments and changes are appended. For consideration of the broad problem we have held to the so-called Doten bill as the type of legislation likely to be considered, and as it will come up automatically this year in the Legislature. This bill provides for no share to be taken by the insurance companies, and puts control in the hands of local mutual companies under state control. This plan lends itself to proper medical organization. It is important that medical affairs should be so arranged that choice of physician, at least within the limits of a very wide panel, be conserved. Central supervision and authoritative inspection are, of course, essential. All these things are considered in the reports above mentioned and need not be gone into here. We have talked over the situation with certain members of the recess committee of the Legislature, and we appeared, all three of us, together with Dr. A. N. Broughton and Dr. J. J. Hurley, at the only public hearing given by that committee and took part in the discussion. We have been informed by Mr. Farnsworth, the chairman, and by Mr. Catheron, another member of the committee, that they will let us know when the time comes (if it does come) for drafting any projected measure, or if there is any other way in which we can be of use. The representative of the State Department of Health on the recess committee, appointed by the Governor, is Dr. W. W. Walcott, of Natick, and we herewith acknowledge and thank him for his very intelligent cooperation with your committee. His presence on the recess committee is very fortunate, and with him there we can keep more closely in touch. We submit this as a report of progress.

F. J. COTTON,  
F. W. ANTHONY,  
W. H. MERRILL.

Dr. G. W. Gay showed to the Council the first book of the records of this Society, beginning with November 1, 1781, and stated that this book and three others, one of the Society records and two of the Council records, the four covering a period of forty-five years, and the small "Charter Book" were being typewritten through the generosity of the president. The official printed records of the Society and of the Council began in the year 1826. Previous to that date, the old books kept in the Society's safe in the vault were the only record of the early history of the Society, and should they be destroyed there would be nothing to show what had taken place in those early days. He hoped that when the typewriting had been completed some friend would come forward with the means for having them printed in a fashion similar to the existing records.

Dr. Gay read the following report on malpractice defense:

#### ANNUAL REPORT ON MALPRACTICE DEFENSE.

The number of cases of threatened suit for alleged malpractice presented to the secretary during the year ending October 1, 1916, was 28. Of this number, 12 were placed in the hands of counsel, 6 applications are in the files, thereby putting them in shape for further action, if necessary, and in 10 cases blanks have been sent and questions have been answered.

Of the 6 active cases referred to in the last report of our legal counsel, as of June 1, 1915, three are disposed of and three are alive, but not active. It may be doubted if they are ever revived.

Thirteen cases have come up this year, of which five have been disposed of. All verdicts thus far have been in favor of the defendant. On finding that the Society defends the suits of its members, many cases have been dropped and others are moribund with little prospect of a revival. The fact that the Society pays no damages, no verdicts, and will pay nothing towards settlement, discourages the shysters and lessens litigation. This is the result of experience in most, if not all the state societies. No hush money is paid to keep a case out of court. It is fight or retire.

The Medical Society of the State of New York has had a medical defense act in force for seventeen years. In over 200 suits no final verdict has, as yet, been returned for the plaintiff. No physician has been called upon to pay damages in any case defended by that Society's attorney. While our cases seem to be increasing, they seem to be decreasing in New York. In 1913 they had 57 cases, in 1914, 55 cases and in 1915, 44 cases. In that state, and doubtless to some extent here, suits are threatened to avoid the payment of the doctor's bill.

The alleged grounds for complaint in our cases are varied and interesting. As might be expected, fractures head the list. Of 19 cases at present, or recently in the hands of our counsel, seven, or more than one third, are of that sort. Four cases had to do with confinements. One suit is pending in which the physician is accused of negligence in permitting exposure to a contagious disease. The diagnosis of syphilis was the ground of another suit, but as the diagnosis was made by our leading experts, there was no difficulty in obtaining a verdict for the defendant.

*Expenses.* The amount paid out by this Society for the defense of its members from January 24 to July 5, 1916 is \$699.02, or an average of about 19 cents

apiece, as against 11 to 12 cents previous to this year. There are various reasons for this large increase, among which mention may be made of the following: The existence of the act is becoming more generally known among our Fellows and they are recognizing the wisdom of availing themselves of its advantages. It has been suggested that perhaps the increase in the number of suits brought, or threatened, is due to the Workmen's Compensation Act. This act has diminished litigation to a certain extent and, as a consequence, some members of the legal profession have encouraged suits against the medical profession more eagerly than formerly.

There can be no doubt that the trend of the times encourages all sorts of tricks to extort money from any defendant, who may chance to have more than the plaintiff. The rich are considered legitimate prey by a large class of people. Get something for nothing. What easier way is there than to threaten litigation with the hope of a settlement, the payment of hush money, or the evasion of a bill?

The object of this medical defense activity is to discourage fake suits and to protect our members from the expense and the annoyance of that sort of imposition. That it is a sane and sensible object would seem to be proven by the fact that about twenty-five state medical societies have adopted the practice and thus far none have repealed the act. This Society has entered upon its ninth year of defending its members in litigation, active or threatened, and time and experience serve only to demonstrate its value.

Dr. A. N. Broughton reported extemporaneously for the Committee on the Workmen's Compensation Act, saying that, on account of pressing professional calls, he had been able to devote little time to the duties of the office of chairman of the committee, an office he had not sought. He suggested that the committee be enlarged, and said that he was not anxious to remain as chairman, suggesting further that the city editors of the newspapers should be approached so that the profession might have a proper representation, and that a trained legislative aid be secured in order to coordinate the needs of the medical profession and to follow this sort of legislation. The need of immediate action by the Council was emphasized by Dr. Cotton and Dr. Dolan, the latter moving that the Central Committee appointed by the "First Legislative Convention of Massachusetts Physicians," held at Worcester, September 20, 1916, be added to the Committee on the Workmen's Compensation Act. (For Central Committee see BOSTON MEDICAL AND SURGICAL JOURNAL, October 5, 1916, p. 513.) The motion was amended to read that those members of the Central Committee who are Fellows of the Massachusetts Medical Society be added to the committee, and that the remaining two members be invited to join with the committee. As amended, the motion was put and passed. The question of providing funds for this committee was discussed by these councillors: Worcester, Clarke, Ward, Kaan, Dolan, Buckingham, Twitchell. Finally, after several plans had been discussed, the following vote was passed:

*Voted*, That the committees on the Workmen's Compensation Act and on Industrial Health Insurance be allowed to expend such sums as they deem necessary, subject to the

approval of the president and the Committee on Membership and Finance.

Dr. G. P. Twitchell presented and explained to the Council proposed amendments to Chapter V of the by-laws, appearing as a committee voted by the Board of Supervisors at a special meeting, held earlier in the day. The proposed amendments suggested by the Supervisors follow:

Page 17, Section 1 (*Board of Supervisors*, line 7, to follow the word "board," this sentence: He shall call special meetings at the request of five supervisors.

Same page, same section, third paragraph (*Diplomas of colleges not on list*, add at end of paragraph, deleting the period, the following: by the district secretary before an applicant is permitted to take an examination.

Same page, same section, last paragraph (*Examinations when held*, second line, delete "at 2.00 p.m."; also next line, change the word "second" to "first" in the two places where it occurs.

Page 18, Section 2 (*How applications are made*), first line, substitute the word "fellowship" for the word "examination."

Same line, after the word "apply," insert the following: on blanks furnished for the purpose, . . .

Same section, end of second line, delete the semicolon and add the following: at least one week before the date of a given examination.

Same page, Section 3 (*Duties of district secretaries*, second line, to follow the word "censors," add the following: shall furnish applicants with blanks adopted by the board of supervisors; they, . . .

Adjourned at 2.19 p.m.

WALTER L. BURGESS,  
Secretary

#### APPENDIX TO REPORT ON HEALTH INSURANCE

CHANGES IN, AND COMMENTS ON THE REPORT OF THE AMERICAN MEDICAL ASSOCIATION COMMITTEE TO THE JUDICIAL COUNCIL OF THE ASSOCIATION OF MAY 15, 1916, BY THE COMMITTEE OF THE MASSACHUSETTS MEDICAL SOCIETY

Section 10, p. 323 of the bulletin

All of your committee favor the proposed plan, but feel that, in the body of the report, it should include all applicants who are engaged in the practice.

Later wording of the bulletin is: "The plan is being tried out by the committee on the health insurance, and the committee on the health insurance is working out the details of the plan." This is a misstatement of the facts.

Section 11, p. 324 of the bulletin  
We feel that the committee on the health insurance should be given the right to select the members of the committee on the health insurance, and that the committee on the health insurance should be given the right to select the members of the committee on the health insurance.

We feel that the committee on the health insurance should be given the right to select the members of the committee on the health insurance, and that the committee on the health insurance should be given the right to select the members of the committee on the health insurance.

Obviously, this scheme will necessitate strong central censorship to avoid padding of bills by unnecessary visits on the part of our few medical undesirables. We feel, however, that this item can be handled:—the lowering of standard inevitable to the "capitation" plan—the plan that has led to the slipshod "lodge" practice we all know,—we feel that this result of a mistaken system cannot be controlled or remedied, and that such a scheme is likely to nullify much of the benefit of the contemplated plan, both as regards patient and physician.

We think there must be a corps of medical referees to adjudicate disputes between injured and carrier as to ability of patient to return to work.

These referees should be appointed by the state central body, not by the locals (as is now done in accident cases).

Provision must be made for payment of these referees,—per case.

The reports of these referees must stand as evidence at hearings.

(If referees are compelled to go to hearings we shall not get the right sort of men to serve as referees at any rate we can afford. This difficulty has already shown itself in cases coming before the Accident Board.)

The question comes up to dentists and dental surgeons—very necessary citizens. They must be taken account of.

Provision must be made to ensure that the referee shall not be the same man as the consultant of the practitioner in charge of the case.

Page 352 of the reprint, lines 8 seq.

We feel that the recommendations here given, sound enough as to big metropolitan hospitals, cannot be made to apply to many hospitals in small or even larger communities, hospitals in which there is no service head, hospitals still run under the old rotating service plan.

Many of these give excellent service, and must be considered.

It is obvious that some provision must be made for employment and compensation of the masseur, the hydrotherapist, etc.,—people we think too little of, considering how indispensable they are.

Pharmacists who turn in bills should in turn be subject to reasonable control.

It is evident that there must be medical inspectors,—local officers,—young medics presumably, who shall have general charge of the local situation, shall refer cases to the central bodies, if they think patients should go to base hospitals, should try light work, should be discharged:—shall report all irregularities. Only with such "scouts" can this scheme be protected from its natural enemies.

Given the right kind of men, their salaries need not be large,—and they would save money.

Change of physicians at the request of either patient or doctor, must be allowed, subject to the rise of the medical inspector.

The question comes up of limitation of work to be done by any one doctor. Obviously, there is a limit beyond which really adequate care is not possible.

We feel, however, that such control should be vested in the central committee.

It is apparently impossible to formulate exact rules as to this.

In a properly equipped company hospital,—as for example the American Steel Wire of Worcester, or even the smaller Gray and Davis plant in Cambridge, one man can do far more work—and do it well,—than is possible to the best ordinary general practitioner with his more meagre equipment. One point, not unimportant, is that the necessary expenses of the central medical committee, the charges for hearings, etc., the expenses for and by medical referees, should not be charged as medical expenses.

They are really part of the administrative overhead, and have nothing to do with medical care of the sick or hurt.

If we bear this in mind, we shall avoid a source

of confusion that has given trouble under our Accident Law.

We feel that there should be a committee of panel physicians in a given locale, to hear disputes, to recommend action to the central committee, but without power to decide.

Such a committee would recommend action to the central commission, to the local board of directors, etc.

We feel that a permanent appointed complaint-committee is preferable for various reasons to a "pick-up" committee.

#### APPOINTMENTS.

DR. CHEVALIER JACKSON of Pittsburgh, Pa., has been appointed professor of bronchoscopy, esophagoscopy and direct laryngoscopy at the New York Post Graduate Medical School and Hospital.

DR. CHARLES W. PILGRIM, superintendent of the Hudson River Hospital, Poughkeepsie, N. Y., has been appointed president of the New York State Lunacy Board.

#### RECENT DEATHS.

DR. FRANKLIN HAVEN CLARK, who died recently at Denver, Colo., was born in Boston on March 17, 1862, the son of a physician. He received the degree of A.B. from Harvard in 1884, and that of M.D. in 1887. Owing to the failure of his health, he never engaged in practice, but after studying for a time in Germany, devoted the remainder of his life to travel, especially in Japan, Italy, and in the Orient. He is survived by his widow, one daughter, and three sons.

DR. JOHN M. EAGER, who died recently at Naples, Italy, was born in New York State in 1854. He received the degree of M.D. from the New York College of Physicians and Surgeons in 1887, and for the next five years practised his profession in Philadelphia. On July 1, 1892, he was appointed assistant surgeon in the United States Public Health Service. He was commissioned surgeon on February 9, 1909, and on August 4, 1912, was assigned to the sanitary office of the American Consulate in Naples.

DR. RUDOLPH VON ELDORF, a surgeon of the United States Public Health Service, who died recently at Lincolnton, N.C., was born in Pennsylvania in 1873. He was well known for his investigations on malaria, typhoid and yellow fever. He had served at various quarantine stations in Savannah, Havana, and elsewhere, and at the time of his death was in charge of the United States Marine Hospital at New Orleans. He is survived by his widow and by one daughter.

#### NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. CENSORS' EXAMINATION.—The censors of the Suffolk District Medical Society will meet to examine candidates for admission to the Massachusetts Medical Society at the Boston Medical Library, 8 The Fenway, on Thursday, November 9, at 4 P.M.

Candidates, who must be residents of the Suffolk District or non-residents of Massachusetts, should make a personal application, at least three days before the examination, to the Secretary, at 355 Marlborough street, between 4 and 5 o'clock, P.M. (except Saturdays and Sundays), and present their medical diplomas.

DAVID CLEVELAND, Secretary.  
Suffolk District Medical Society.

## Address.

### ANTERIOR POLIOMYELITIS.\*

By A. J. McLAUGHLIN, M.D., BOSTON.

Surgeon, U. S. Public Health Service; Commissioner of Health of Massachusetts.

#### CAUSE OF THE DISEASE.

ALTHOUGH much remains to be learned in regard to poliomyelitis, certain facts have been demonstrated beyond question. The disease is caused by the presence in the central nervous system of a minute microorganism which belongs to the group capable of passing through a Berkefeld filter. The organism or virus is cultivable *in vitro* on suitable media. The virus from human cases is pathogenic for apes, producing characteristic symptoms similar to those observed in human cases. The rabbit is susceptible though he is apt to prove refractory, and if symptoms are produced, they differ markedly from those observed in man. The guinea pig has been reported to be susceptible at times. No other animals are known to be susceptible.

#### SOURCE OF THE VIRUS.

The only known source of the virus is the human body, although the possibility of another reservoir in some animal must be considered. In persons dead of poliomyelitis the virus has been

found in the brain, spinal cord, mesenteric glands, tonsils, and secretions of the nasopharynx and intestines. In acute cases the virus has been found in the secretions of the nasopharynx and washings from the rectum. It has also been found present in the secretions of the nasopharynx and intestines in convalescents after several weeks or even months, and in the nasopharyngeal secretions of apparently healthy persons who had been exposed to infection. The virus has been recovered from dust in rooms occupied by patients with poliomyelitis.

The demonstrated sources of infection are therefore:

- Persons ill with poliomyelitis.
- Convalescents.
- Healthy carriers.

#### TRANSMISSION.

The question of the mode of transmission of the virus from its reservoir to the susceptible individual is still in doubt, but it is probable that it may be transmitted by direct contact with the secretions of the infected individual. It has been found that the virus may survive for several weeks in a solution of saline.

The virus has been found in the secretions of the nasopharynx and intestines of convalescents after several weeks or even months, and in the nasopharyngeal secretions of apparently healthy persons who had been exposed to infection.

\* Delivered at a joint meeting of the Boston Medical and Surgical Association and the Massachusetts Homœopathic Society, held at the Hotel Marlborough, Boston, October 19, 1916.

iologic observations, while appearing to support in some particulars, in other phases tend to make such a conclusion impossible.

Very often laboratory experiments do not represent natural conditions, but some of the possible modes of infection of monkeys, demonstrated by laboratory experiment, approach natural conditions and suggest the most feasible and probable portal of infection. Monkeys may be infected by rubbing the virus upon the nasal mucous membrane, and this suggests a possibility of easy infection through the nasopharynx under natural conditions.

Frost\*, in his scholarly monograph, makes the following sane and logical deduction:

"On the whole the experimental evidence, taken alone, while not excluding other means of transmission, points to the conclusion that poliomyelitis is a contagious disease, spread from person to person through interchange of infectious secretions, the sources of infection being the clinically definite and clinically indefinite acute cases of poliomyelitis, convalescents, and passive human carriers."

#### EPIDEMIOLOGY.

A brief review of its epidemiologic peculiarities will illustrate the contradictory and variable nature of its manifestations in the field.

#### GEOGRAPHIC DISTRIBUTION.

Poliomyelitis is of world-wide distribution. Its outbreaks have occurred in every climate from the equator to the North Temperate Zone. It is true, however, that it has been reported more constantly and in greater evidence in the northern than in the southern states of the Union.

#### SEASONAL PREVALENCE.

The seasonal prevalence of poliomyelitis is more characteristic than any of its other epidemiologic manifestations, with the exception of its age incidence. It reaches its maximum in August and September, although cases are reported in every month of the year in Massachusetts. Its seasonal prevalence resembles that of diarrhea and enteritis of children, and typhoid fever. The presence of the virus in the intestinal contents strengthens the analogy. Its seasonal prevalence also corresponds to the period of greatest activity of mosquitoes and flies, and, therefore, is consistent with the theory that biting insects are a factor in its causation. Some observations have seemed to show a relation between dust and dry seasons and the outbreaks of poliomyelitis. On the other hand, it has been prevalent in wet seasons and in wet climates.

It must be remembered that this disease is not confined to summer or early autumn. We not

only have it every month in the year, but its endemic prevalence is probably much greater than reports show. Race, nationality and sex show no marked or characteristic influence. Social and economic factors seem to play a small part in its transmission. Cases are reported from the homes of the rich, the well-to-do, and the poor. The sanitary conditions surrounding the home do not seem to be a determining factor.

#### PECULIAR MANNER OF SPREAD.

Most diseases spread in a regular progression along the lines of travel. This applies even to those diseases which are transmitted by insects. This is not always so with poliomyelitis. It may be epidemic in Washington, evade Baltimore, and attack Philadelphia; or, as Frost pointed out, the epidemics of 1908, 1909, and 1910, in Minnesota, Iowa and Nebraska, were commonly regarded as sequelae of the New York epidemic. Chicago, however, through which practically all travel to these states from New York passed, escaped.

On the other hand, there are instances of rapid spread over a wide area, apparently on radial lines from a central focus, as the Iowa epidemic of 1910, and the Swedish outbreak in 1905, described by Wickman. We have instances of rapid radial spread which suggest man as the carrier, but there are also the instances difficult to explain, of exemption of cities most exposed to infection through travel, as Baltimore, in 1910.

This same peculiarity of sparing an intervening city between two badly infected cities is noted in the spread of cerebrospinal meningitis. The peculiar distribution of poliomyelitis and small total incidence in the population find an analogy in some plague epidemics, but its age incidence is totally at variance with that of plague.

#### SMALL NUMBER OF PERSONS ATTACKED.

Less than 1/10 of 1% often represents the attack rate in an outbreak, or less than one person per thousand of the population. This peculiarity has not been explained, although two logical explanations have been suggested,—either that the amount of susceptible material is limited by some immunizing influence, or that its transmission is devious and selective, involving possibly an animal reservoir and an insect transmitter.

#### URBAN AND RURAL PREVALENCE.

The prevalence of the disease seems to be greater in rural and suburban districts than in cities. It must be conceded that most of these observations have been made in epidemics rather than in times of endemic or low prevalence.

\* Frost, Wade H.: Poliomyelitis. Reprint No. 350, Public Health Reports, Washington, 1916.

## AGE INCIDENCE.

The most consistent epidemiologic characteristic of poliomyelitis is the age incidence. In a mass of contradictory and irregular manifestations only the seasonal prevalence and age incidence are consistent. The great majority of the cases are children under five, a smaller group from five to ten, a few from ten to twenty, and only rarely over twenty.

Assuming that poliomyelitis is a communicable disease, transmitted from person to person, if the rural prevalence is higher in epidemics than the urban, it follows that there must be relatively more susceptible material in the rural districts. It is reasonable to suppose that some immunizing influence, operating more constantly and more actively in the city, cuts down the amount of susceptible material. What is the nature of this influence? Is it due to an increased resistance coming on with age, or is it due to an active immunity acquired by having had the disease in a light or abortive form? It has been demonstrated that convalescents and healthy carriers harbor the virus in the nasopharyngeal secretions for weeks and months. It has also been shown that in apes the nasopharynx, with its close relation, through the lymphatics, with the central nervous system, is an easy portal of entry, and monkeys inoculated intracerebrally have shown that the nasopharynx is also a point of egress for the germs. We have here all the conditions for the widespread distribution of the virus.

In all recent epidemics light and abortive cases have been shown to be numerous. It is not unlikely that these light cases, which ordinarily pass unrecognized, without paralysis, or paralysis of the most fleeting character, constitute a larger part of the total morbidity than the frank paralyzed cases. In considering the possibility of an active immunizing influence, we must concede also the possibility of variations in virulence, not alone as among individuals attacked, but variations in virulence of the outbreaks themselves. Variations in virulence exist in practically all microorganisms, and the virus of poliomyelitis is no exception. The difference noted in individual cases in the severity of the attack may be due to a complex set of conditions, involving not only the infecting agent, but also the susceptibility or self-protective power of the individual. Differences in type of an entire epidemic, however, while their cause may be complex, also undoubtedly occur. The fatality rate of epidemics of other diseases varies greatly, it often being lower in centers where the disease has been active over the longest period. Smallpox varies from a mortality of 15 to 30%, to the mild form, practically without deaths, which in the South was called "Cuban itch." Immunity is conferred by Cuban itch, as well as by a severe case of smallpox. It is not improbable that an active immunizing influence is going on constantly, con-

stituting an endemic prevalence of this disease, with relatively few paralyzed cases.

This hypothesis would best explain the age-incidence of the disease, for with a widespread infection, opportunity for immunity is afforded in the first years of life. Theoretically, such a process of immunization would be most active where opportunities for contact were greater, viz: the city. We should have a higher percentage of immunes in the city, and a lesser percentage of susceptible individuals. If this reasoning were sound, we should not only have a lesser number of immune people in the country, but the susceptible group should have a higher age-limit. Is this the case?

The difficulty of separating rural from urban districts is recognized. Statistics are not available at present in Massachusetts in sufficient amount or of a proper character to warrant positive conclusions. I made an effort to determine whether the age limit of those attacked was the same in rural and urban outbreaks. A group of about 20,000 persons in 15 towns where poliomyelitis has occurred, ranging in population from 427 to 22,135, was taken and compared with the worst stricken of our smaller cities, North Adams. The population of the rural group is 23,361; that of North Adams, 22,039. The attack rate was very nearly the same, as there were 19 cases in the rural group and 21 in North Adams.

	Popula- tion	Total Cases	Under 5	5 to 10	10 to 15	15 to 20	Over 20
Rural Group	23,361	19	7	5	3	1	3
North Adams	22,039	21	16	5	0	0	0

In round numbers the percentage may be expressed:

PERCENTAGE OF TOTAL CASES.			
Rural	Under 5	5 to 10	Over 10
Rural Group	37	26	37
North Adams	76	24	0

This difference is striking, and although based on a comparatively small group, is suggestive that the age limit of susceptible age groups may be higher in rural and suburban life. The relation between the percentage of susceptible persons and the age limits of the susceptible group should be studied further. It is reasonable to suppose that, if the opportunities for immunity are less, one would expect a larger proportion of susceptible persons and a higher age limit in the group. For example, measles is ordinarily limited to the lower age groups, but if introduced into virgin soil it attacks all ages, and the immunity of adults in our cities is probably due to infection during the earlier years of life. It would be interesting to determine in a large group of thousands of cases of measles, scarlet fever and poliomyelitis, not only what the real relation between rural and urban prevalence is, but also what percentage of the total is found in the various age groups in city and country.

We have had our share of dreams and theories in this disease. Its analogy in one given particular to another disease has been sufficient to create a theory showing its transmission to be due to the same agencies. As a filterable virus, it suggests yellow fever, and its seasonal prevalence corresponds with the period of greatest activity of the mosquito. It also commonly declines with the advent of cool weather. But yellow fever stops with the first frost, and can start again only when new material is introduced from without, and in the presence of mosquitoes. Poliomyelitis declines in prevalence in the autumn, but continues at a lower rate throughout the winter months, so that the mosquito, even if shown to be a factor in increasing the prevalence in July, August or September, must be exonerated from blame in transmitting the disease through the winter months.

Poliomyelitis bears a certain analogy to rabies. Its predilection for nerve tissue, and what at times at least seems like a protracted incubation, suggest rabies, but evidence is lacking to show that the resemblance goes any further.

Its resemblance to plague in its spread and distribution of cases, lack of secondary cases, etc., has been noted, and the rat and flea combined would explain many of the peculiar epidemiological manifestations of this disease. It is difficult, however, to reconcile its peculiar and consistent age incidence with a flea-borne disease, in which you would expect persons of all ages to be bitten.

This review of the epidemiologic features of poliomyelitis and the known facts in its etiology accentuates the baffling nature of the problem, from the point of view of the health officer. With cholera, plague, yellow fever, he has precise knowledge and can act accordingly, with the expectation of definite results. In poliomyelitis there is no certainty of the details of transmission, no simple diagnostic procedure, no feasible method of determining carriers or the presence or absence of immunity. What we need now is not more theory but more research work, both in the laboratory and in the field, to eliminate or confirm the various theories.

It is well to remember in our research work that a positive result under artificial conditions may be given too much weight in its application to natural conditions. On the other hand, a negative result should not be considered conclusive. Many eminent workers failed to transmit measles to monkeys and others succeeded, because former negative results did not deter them. Often, too, laboratory workers expect the same symptoms in one animal as are presented in man or in the ape.

It is imperative that we be able to find the abortive light cases and carriers. As practical health officers we need a diagnostic procedure that is reasonably specific and comparatively easy in technique to determine the presence of the disease. This is needed, not only in the interest

of the patient, but early diagnosis is essential for the protection of the community in detecting carriers and light cases. We also need a diagnostic procedure reasonably easy of application which will determine the presence or absence of immunity, such as the Schick test does for diphtheria.

There are other needs and possibilities which suggest themselves, a prophylactic for active immunization, and a serum treatment of the disease itself. Two misleading tendencies are apparent, one—general—to look for the facts of this disease in epidemic times only, overlooking its probable endemic prevalence; two—individual—to expect paralysis in every case. To correct these tendencies we need a careful study of diseases of children, including especially diarrhea and enteritis in children under two years of age, regardless of the presence of an epidemic, and we need, not alone the means of accurate diagnosis, but a general willingness to accept this diagnosis in the cases in which paralysis is not apparent.

In the face of our incomplete knowledge, this is no time for dogmatic utterance. We must not eliminate theories or hypotheses, however fantastic, upon mere opinion. We need facts and methods, and careful research work is the only way in which these essential facts and methods of diagnosis can be secured.

#### THE OCCURRENCE AND DIAGNOSIS OF PERICARDITIS.\*

By EDWIN A. LOCKE, M.D., BOSTON.

THE infrequency with which pericarditis is seen clinically, in comparison with the relative frequency of its recognition at the autopsy table, is a striking and singularly significant fact and has led to the statement by one prominent medical writer that the diagnosis of pericarditis is usually a post-mortem one. Although regarded as one of the rarer of the cardiac affections it is without doubt far more common than supposed and by reason of its high mortality should rank next to endocarditis in importance among the cardiac diseases.

Several evident facts can be stated to explain, at least in part, the failure to diagnose such a large proportion of the cases of pericarditis:—

1. The changes in the pericardium, except in the case of direct trauma, nearly always occur as a complication during the course of some other disease. Indeed, it is doubtful if pericarditis is ever primary except in the case of injury or possibly in rare instances of in-

\* Read at the meeting of the Boston Medical Library in conjunction with the Suffolk District Medical Society, Feb. 16, 1916.

fection of the sac by the tubercle bacillus. The cause of the symptoms manifested being known, it is but natural that a complication which too often presents no obvious symptoms or signs should be overlooked.

2. Pericarditis in a majority of cases occurs as a late complication, often terminal, when examination of the heart is most difficult and unsatisfactory and the presence of predominant signs in the chest obscures those due to the involvement of the pericardium. Not infrequently the patient is too sick to be examined thoroughly.

3. Certain types of pericarditis frequently give no characteristic signs or symptoms, those present being reasonably accounted for by the primary disease. In other words, many of the symptoms and signs of pericarditis are common to other intrathoracic diseases, especially those of the heart.

4. Signs, when present, are largely subjective.

5. Perhaps most important of all, the possibility of pericardial involvement is usually, I believe, forgotten and any suggestive symptoms and signs in consequence attributed to the already known condition.

#### AUTOPSY STUDIES.

In an effort to determine as exactly as possible the incidence of this disease among hospital cases, and the possibility of more frequent diagnosis, I have made a careful study of the autopsy reports at the Boston City Hospital for the past nineteen years together with the clinical records of the same cases. I shall confine myself in this brief paper to a discussion of these results and to a consideration of some of the more essential points in diagnosis, in an effort to emphasize the importance of the disease clinically.

The total number of post-mortem sections made during the nineteen years (*i. e.* from 1897 to 1915 inclusive) was 3,683. In this series acute lesions of the pericardium were described in 150, and chronic lesions in 209 instances. Exclusive of these 359 cases of true pericarditis, 88 showed milk patches in the pericardium.

The above figures show that acute pericarditis was found in 4% of all autopsies.

In a rather careful search through the literature on pericarditis I have been able to find but few statistics of this nature. Wells<sup>1</sup> gives quite similar figures. Among 1,048 autopsies on adults he found evidence of acute inflammation of the pericardium in 57, or 4.5%, and chronic inflammation in 71, or 6.8%, a total of 128 cases, or 11.3%. In 220 necropsies at the Boston Consumptives' Hospital on individuals dying of tuberculosis 16, or 7.3%, showed pathologic processes in the pericardium. These rather astonishing figures indicate that pericardial complications must be relatively common clinically and especially since a large percentage of cases with pericarditis do not succumb.

A comparison of the above figures with similar ones for acute endocarditis emphasized still further the clinical importance of pericarditis. In the above mentioned 3,683 autopsies, acute endocarditis was described in 185, or 5%, and chronic endocarditis in 462, or 12.6%, making a total of 647 cases of acute and chronic endocarditis, or 17.6%. If this series of 3,683 be accepted as representative, which seems reasonable, we may say that the relative frequency of acute pericarditis and endocarditis as found at autopsy is in the ratio of 1:5 and in the case of the chronic lesions of 5:7:12.6, or, if the acute and chronic cases are combined, of 9:7:17.6.

With the purpose of gaining some definite idea of the possibility of accuracy in the diagnosis of pericarditis I have examined all the clinical records of the 150 cases of the acute form. In only 27 instances, or 17%, is there any clear evidence in the clinical notes of the presence of disease of the pericardium. In the majority of cases the data are very meagre and exact inference as to the type and extent of the lesions is consequently impossible. A detailed study of the particular types of pericarditis found reveals an even greater deficiency in the clinical work. The most glaring errors are in the cases of pericarditis with effusion of various forms. There was a total of 17 cases, with an effusion of 200 c.c. or more, the amount varying from this minimum to a maximum of 1,000 c.c. In not a single instance does the history contain any positive diagnosis of the effusion and in only 3 is the description even moderately suggestive of fluid. The 3 cases with the largest effusion, *i. e.* 500, 750 and 1,000 c.c., were unsuspected if one may judge by the records. A rub was mentioned in only 2 instances among 42 cases of fibrinous pericarditis.

One must admit that these statements are somewhat unfair to the clinician as no allowance is made for incomplete clinical notes, yet after generous allowance is made it must be admitted that the record is an astonishing one. In at least 50% of cases, I believe, it should be possible to diagnose the condition with reasonable certainty.

Greater accuracy in diagnosis means that of all a general knowledge of the relative frequency of the various types of pericarditis of the diseased condition with which pericarditis is commonly associated. In the following table are given the 159 pericarditic autopsies of pericarditis described in the clinical records according to the type of lesion.

TABLE I.

TYPES PERICARDITIS	No. CASES	ACUTE		CHRONIC	
		PERCENT- AGE	No. CASES	PERCENT- AGE	
Fibrinous	42	28.00	17	8.13	
Serofibrinous	33	22.00	82	39.24	
Haemorrhagic	4	2.67	5	2.39	
Purulent	39	26.00	3	1.44	
Tuberculous	0	0.00	5	2.39	
Adhesive—partial	14	9.33	30	18.66	
Adhesive—total	18	12.00	57	27.27	
Calcified	0	0.00	1	.48	
TOTALS	150	100	209	100	

It will be noted that in the group of acute cases the largest number are of the so-called fibrinous type although the fibrinous, serofibrinous, purulent and adhesive forms are found with about equal frequency, the limits being 21.33 and 28%. The serofibrinous, purulent and haemorrhagic, which we recognize clinically as pericarditis with effusion, together represent 50.7% of the total acute cases.

Among the chronic types the serofibrinous and adherent forms distinctly predominate. This last mentioned group comprises approximately 46% of the total.

These figures show a close correspondence with those of Breitung<sup>2</sup> (Table II) who found 324 instances of acute and chronic pericarditis among the post-mortem cases at the Berliner Charité during a period of eleven years.

TABLE II.

TYPES	No. CASES	PERCENT- AGE	
Pericarditis serofibrinosa	108	33.33	
Pericarditis haemorrhagica	30	9.26	
Pericarditis purulenta	24	7.41	
Pericarditis tuberculosa deuteropathica	24	7.41	
Pericarditis tuberculosa idioopathica	2	.62	
Pericarditis adhaesiva partialis	111	34.26	
Pericarditis adhaesiva totalis	23	7.09	
Pericarditis ossificans	2	.62	
SUMMA	324	100	

It seems probable that among the cases seen clinically in a general hospital the fibrinous type predominates to a far greater degree than would appear from pathologic statistics. As a rule they are the mildest and occur with the less seriously ill patients with whom recovery is unquestionably much more common.

In the fatal cases of pericarditis with effusion, at least, the serous and the purulent forms of the acute type seem to play approximately equal parts, as indicated in Table I, while in the chronic cases serous fluid is almost invariably the type of fluid present. True haemopericardium is rare in both the acute and chronic cases although blood-tinged exudate is by no means uncommon. Including the 4 cases of true haemorrhagic pericarditis, blood-tinged fluid was found in 17 instances, or 11%, and in association with the following primary diseases: nephritis 3, septicaemia 2, empyema 2, aortic aneurysm 1, rheumatism 1, pneumonia 1, tuberculosis 1, and unclassified 6. Among the chronic cases, and including the five cases of true haem-

orrhagic pericarditis, the fluid was of this form in only nine, or 4%. Pericarditis with effusion in the aged is said to be commonly haemorrhagic. (Osler.) This does not hold true in the cases tabulated above.

#### THE PRIMARY DISEASE IN PERICARDITIS.

The question of the nature of the primary disease in pericarditis is naturally of first importance to the clinician as especially indicating the conditions under which pericarditis most frequently arises. Wells<sup>3</sup> gives the possible channels of infection to the pericardium as follows:—1. the blood stream; 2. the lymph vessels; 3. direct infection by trauma; 4. by extension which must be from, *a.* heart or blood vessels within the pericardium; *b.* mediastinum; *c.* pleura; *d.* peritoneum. With these various possible modes of invasion it is obvious that pericarditis may arise in the course of a very large number of diseases. Any attempt at classification of these primary diseases is unsatisfactory but in the interest of conciseness I shall offer the following grouping:

1. *Trauma and perforation of the pericardium.*
2. *Infectious diseases* (e. g. rheumatism, chorea, pneumonia, tuberculosis, meningitis, scarlet fever, influenza, smallpox, typhoid, syphilis, gonorrhoea, actinomycosis.)
3. *Local or general septic processes* (e. g. septicaemia, pyaemia, osteomyelitis, tonsillitis, erysipelas, local abscesses.)
4. *Chronic diseases, usually as a terminal complication* (e. g. nephritis, advanced tuberculosis, carcinoma.)
5. *Chronic intoxications and poisonings* (e. g. gout, diabetes, phosphorus poisoning.)
6. *Extension or irritation by contiguity from neighboring structures* (e. g. diseases of mediastinum, pleura, lungs etc.)
7. *Affections of the heart and aorta* (e. g. endocarditis, affections of the myocardium, aortic aneurysm.)
8. *Blood diseases and haemorrhagic diatheses* (e. g. severe anaemia, leucaemia, haemophilia, purpura, scurvy.)

The majority of all cases of pericarditis are found associated with only a few of the conditions mentioned above. Taking into consideration all ages rheumatism is unquestionably the commonest cause. The infrequent finding of this condition at autopsy secondary to rheumatic fever is easily explained by the fact that this disease seldom runs an acutely fatal course, death, if occurring, being due to complications of long standing. In the 150 cases of acute pericarditis studied at the Boston City Hospital, rheumatism was evident as the primary disease only twice. Autopsy statistics of chronic pericarditis show a considerable percentage to be due to this disease. On the other hand the incidence of pericarditis in acute rheumatism, as given by different authors, varies within rather

wide limits (Latham 13%, Peacock 16%, Sibson 19%, Pye Smith 22%, Whigham 17%, Osler 6%).<sup>4</sup> The total number of cases of acute rheumatism included by these authors is 2,080 and the occurrence of pericarditis 344, or 16%. Eichorst places his estimate as low as 3% and von Schrötter as high as 30%.<sup>5</sup> Huchard quotes the statistics of many authors on this point which vary from a minimum of 10 to a maximum of 75%. All authorities are agreed that acute rheumatism as an etiologic factor is largely confined to youth and early adult life.

Pericarditis occurs with such a considerable variety of other diseases that it is difficult to give any precise statement of their order of frequency. In adults pneumonia and pleurisy probably come next to rheumatism in importance. With the former disease the type of pericarditis is often frankly purulent although in some instances the pneumococcus may be recovered from the exudate in the absence of pus. These cases even when purulent are, furthermore, not always fatal. The development of pericarditis with pneumonia is quite directly dependent on the severity and extent of the process in the lungs, being most common in those cases with bilateral involvement and more frequent with consolidation of the lower than of the upper lobes.

Septic processes, especially septicaemia or pyaemia, and those of the pelvic organs or bones, quite commonly lead to pericardial complications and are particularly prominent in the fatal cases. The pathologic type of changes in the pericardium is variable but the exudate is commonly purulent although a rather large percentage of the cases of adherent pericardium are of this origin.

Pericarditis is generally acknowledged to occur with nephritis, but it is difficult in many instances to establish a definite relationship between the two. Some authors consider nephritis to be a very common cause of the condition, while others regard it as rare and due not to the disease in the kidneys, but to some associated pyogenic process. It is especially observed with the chronic nephropathies. Any type of pericarditis may occur and if an effusion is present, it is sometimes haemorrhagic.

A less common cause of pericarditis is tuberculosis of the thoracic organs or acute miliary tuberculosis. The changes in the pericardium may be identical with those found in association with other diseases or be strictly tuberculous.

TABLE III.

TABLE OF 150 AUTOPSY CASES OF ACUTE PERICARDITIS ARRANGED TO SHOW THE NUMBER OF THE DIFFERENT TYPES OCCURRING WITH VARIOUS DISEASES.

NUMBER OF CASES OF EACH TYPE OF PERICARDITIS.

PRIMARY DISEASE	EFFUSION	SPERMATOPHYTES	ABSCESSES	ADHERENT PERICARDIUM	HAEMORRHAGIC	TOTAL
Pneumonia	20	13	20	5	5	63
Empyema	1	5	1	1	1	6
Abscess Lung	1	1	1	1	1	1
Aortic Aneurysm	2	1	1	1	1	5
Acute Endocarditis	1	1	1	1	1	1
Tuberculosis	1	2	2	1	1	7
Local or General						
Sepsis	10	6	9	1	1	28
Nephritis	1	4	2	3	3	16
Meningitis	1	1	2	1	1	3
Rheumatism	1	1	1	1	1	2
Cirrhosis Liver	1	1	1	1	1	1
Not Determined	1	5	1	1	2	17
TOTALS	63	33	62	14	14	150

In how large a percentage of these the involvement was terminal and thus due to secondary infection it is impossible to say, but from a careful reading of the clinical histories and study of the autopsy reports, it is evident that the percentage is a rather large one. Pneumonia, empyema and abscess of the lung together comprise 47%.

It is difficult to state exactly the relation of age to the incidence and type of pericarditis. Statistics show that the disease is much more common in childhood than in adult life. In infancy, broncho-pneumonia and empyema play the most important rôle as etiologic factors. Throughout childhood rheumatism remains at the head of the list. During early adult life, the most frequent causes are rheumatism, pneumonia, tuberculosis and bone diseases. After thirty, rheumatism is relatively rare while pneumonia becomes an increasingly important cause. In old age, pneumonia and chronic nephritis are the most frequent. Blechman.<sup>6</sup> At all ages septic processes figure prominently in the etiology.

TABLE IV.

TABLE OF 150 AUTOPSY CASES OF ACUTE PERICARDITIS ARRANGED BY AGE PERIODS ACCORDING TO PRIMARY DISEASE.

PERIOD OF LIFE	Infancy	Childhood	Adolescence	Early Adult	Adult	Old Age	Total
Pneumonia	1	4	8	14	6	7	40
Empyema	1	1	1	1	1	1	6
Abscess Lung	1	1	1	1	1	1	6
Aortic Aneurysm	1	1	1	1	1	1	6
Acute Endocarditis	1	1	1	1	1	1	6
Tuberculosis	1	2	1	1	1	1	7
Local or General							
Sepsis	10	6	9	1	1	1	28
Nephritis	1	4	2	3	3	3	16
Meningitis	1	1	2	1	1	1	7
Rheumatism	1	1	1	1	1	1	6
Cirrhosis Liver	1	1	1	1	1	1	6
Not Determined	1	5	1	1	2	1	17
TOTALS	17	28	37	41	28	23	150

## SYMPTOMS AND SIGNS OF PERICARDITIS.

I shall discuss briefly only the more important of the symptoms and signs of pericarditis. The symptoms of this condition are seldom characteristic and it is, perhaps, the rule that an unsuspected pericardial involvement is found on careful routine examination or because sought for in those diseases with which it is known to be frequently associated. At other times the possibility of trouble in the pericardium is suggested by the sudden increase in the severity of the symptoms during the course of a critical illness. In spite of the most careful observation, however, definite evidences of the disease may be entirely absent throughout its course. West<sup>7</sup> has particularly called attention to these last mentioned cases which he speaks of as the "latent type." Chronic pericarditis, and especially the adhesive form, is often found post-mortem without any suggestion of the condition having been present during life. He further speaks of certain acute cases where the process is confined to the posterior portion of the pericardium and therefore friction sounds never become audible or only many days after the appearance of symptoms which make the diagnosis probable. West considers that latent cases are very commonly due to gout or chronic nephritis.

The clinical picture is difficult to give. It depends on many factors, but chiefly, the nature of the process, whether acute or chronic, the character and amount of the exudate, the condition of the heart muscle and endocardium and the presence or absence of complications (Sinnhuber).

In not a few, the onset is more or less well marked. The patient becomes restless, breathes with a shallow, rapid respiration, looks distressed and anxious, the face has a dusky pallor, and he often complains of pain or oppression in the region of the precordia. Nausea and vomiting, which are rather common late symptoms in the fatal cases, are occasionally met with at onset. Bramwell, in speaking of the onset of pericarditis says, "the experienced eye can often detect that something has occurred, that the patient is not so well as he was at the previous visit"; and this, I think, expresses very well the vague clinical picture which is often presented. An initial chill is rare. Pain so often met with as an initial symptom, varies from a vague sensation of pressure or distress in the region of the precordia, to the most intense and agonizing stabbing character. Sibson<sup>8</sup> observed pain in 70% of his cases. It is said to be most common in pericarditis with effusion although in this same type pain may be entirely absent from first to last. If pain appears early it invariably disappears with the development of an effusion. Epigastric pain may be present with large effusions (Sibson). Especially in children pressure over the precordia or deep inspiration frequently increases the pain, rarely also the skin may

be extremely hyperaesthetic. Pressure in the epigastrium just below the xiphoid cartilage or at the costal angles often induces a severe pain reaction. The temperature is apt to show a more or less definite rise with the beginning of inflammation in the pericardium but is in no way characteristic.

The pulse and respiration are much more disturbed as a rule ("Perverted pulse-respiration ratio," West).<sup>9</sup> Sometimes the respiration reaches 60 or 70 per minute and is excessively labored and shallow. Shortness of breath is common and with large effusion often becomes extreme orthopnoea. Cases of paroxysmal dyspnoea have been described.

With marked effusion the patient often assumes a sitting posture and sometimes will be found with the legs and thighs strongly flexed and resting with the arms on the knees. Hertz<sup>10</sup> describes this as an important sign of pericarditis with effusion and terms it the "knee-chest sign." Wynter<sup>11</sup> lays particular stress on the absence of abdominal respiration as a sign of pericarditis. He states that the diminution in respiratory movements in case of diseases of the lungs and pleura is usually not marked and is one-sided, but in pericarditis it is bilateral and often entirely absent. This author considers it frequently to be as marked as in abdominal diseases but always rigidity and general tenderness are for the most part lacking. This diaphragmatic paresis he explains on the grounds of reflex inhibition due to involvement of the diaphragm secondary to inflammation in the pericardium. His observations lead him to consider it one of the earliest and most reliable of the symptoms of pericarditis and quite as common with the fibrous as with the serofibrinous form. It affords a reasonable explanation of the upright position so frequently taken by the sufferer.

Cough of a short, irritative, spasmodic character may be present as in pleuritis.

The initial excitement and restlessness may give place to a more or less marked condition of drowsiness after pericarditis is well established. Delirium, even of a most intense nature, is occasionally seen, and rarely coma.

Later symptoms of pericarditis depend largely on two general factors: first, the degree of cardiac embarrassment, and second, pressure from the distended pericardial sac. The first condition is chiefly caused by paralysis of the diaphragm and direct influence on the heart muscle in consequence of the local inflammation. The pericardial sac is firm and inelastic but, when inflamed, is easily stretched, and consequently an enormous effusion may cause very few cardiac symptoms (MacKenzie). Cardiac disturbances, such as extra systole and auricular fibrillation, are probably due not to the pericarditis but to a preëxisting diseased myocardium (Cowan).

The symptoms from pressure from the distended sac are among the latest and most severe. Through pressure on the lungs, the breathing

is especially embarrassed, leading to the intense dyspnoea or orthopnoea, cough, etc., mentioned earlier. Venous engorgement, especially of the veins of the neck, may reach an extreme degree, while cyanosis may be more intense than is seen in almost any other condition. Oedema is rare. Pressure on the left recurrent laryngeal, as in aneurysm and mediastinal growths, probably explains hoarseness and aphonia. Hiccough is occasionally seen and is probably the result of pressure on the phrenic nerves at the point where they pass down over the pericardium. Difficulty in deglutition is at times observed and swallowing may be impossible except in the sitting posture.

#### PHYSICAL SIGNS.

The physical signs of pericarditis are hardly more numerous than the symptoms but in general are much more characteristic and important. To a greater degree it is true that the signs vary considerably with the type of lesions and degree of involvement present.

In the early stages the first and most important sign is the friction *frmitus* or rub. The type of friction and its intensity depend on the nature of the exudate and force of the heart's contraction, and is variously described as "rushing," "rustling," "whiffing," "harsh," "rough," "grating," "creaking," "scratching," etc. In its general quality it may resemble closely the pleural rub. As a rule the friction murmur is double, the "to and fro" sound, though fairly commonly it occurs as a single sound or very rarely triple, the "cantering horse" type. Occasionally it is practically continuous and so prominent as to obscure the heart sounds completely. In time the sounds, although often described as synchronous with those of the heart, are not quite so, hence the terms "mesosystolic" and "mesodiastolic" employed by some authors. Sibson emphasizes the fact that the pericardial sounds never begin or end with a shock and are characterized by the same intensity throughout. They may be intensified, however, by any increase in force of the heart's contraction, by sitting forward when upright or rarely by taking the recumbent position. They appear superficial and pressure of the stethoscope may occasionally augment the intensity.

In contrast to endocardial sounds they have no definite area where they are best heard nor paths of conduction. The commonest areas where they are heard are at the base and over the middle portion of the heart. It is usually stated that these sounds are never audible beyond the area of cardiac dullness or in the back, but a sufficient number of cases are reported to make it seem probable that in a not insignificant percentage the rub is heard over a relatively wide area of the thorax and in the lower left back also. Panly,<sup>12</sup> Devie, E. et Gardère, C.,<sup>13</sup> Paviot, J. et Delaetanal, J.,<sup>14</sup> and others have discussed this subject at length. In cases where the rub is heard beyond the heart limits, propaga-

tion is chiefly by the hypertrophied heart which is held close to the chest wall, but also to a varying extent by the thorax wall, indurated lung or possibly to some extent by the liver. The fact that friction is seldom audible in the back is not due to the fact that the posterior part of the pericardium is not involved, but because the sounds are successfully muffled by the interposed lower lobe of the left lung. When they do appear in this region the explanation is probably to be found in the fact that the greatly enlarged heart or the presence of a pericardial effusion either push the lung aside, or more probably render the lower lobe atelectatic in either case, the conditions being more favorable for the transmission of the sound. The murmur thus heard in the back is not transmitted from the anterior surface but produced in the posterior part of the pericardium. An especially important consideration is the fact that the rub may be present for only a very brief period, and thus escape observation.

A tactile thrill over the pericardium of a harsh, vibratory character, is a familiar sign (Sibson, 20%). It is felt over the same area as the audible friction. As in the case of the friction sounds it is apt to be transitory and change from day to day.

With the development of effusion of any force other more or less characteristic signs may appear. In youth, where the chest is still pliable, bulging over the region of the precordium is sometimes seen, likewise with large effusion the epigastrium may appear full and immoveable.

With the accumulation of fluid, the palpable impulse ordinarily weakens, is more diffuse and moves upwards, at times reaching the third space. Coincidentally the heart sounds become weaker and muffled. West<sup>15</sup> believes that one of the first results of pericarditis is involvement of the adjacent muscular tissue of the heart and consequently dilatation of this organ which is a factor in the alteration in the cardiac sounds. The friction sounds may or may not disappear as the fluid increases.

The amount of effusion necessary to be recognizable is a matter of some difference of opinion. Probably at least 150 to 200 c.c. must be present to give definite percussion signs. Small effusions

The shape of the fluid-filled pericardium is mapped out by light percussion. The limits are described as pyriform or oval and the fluid limits are much larger than the heart limits, and, even in the extreme cases, the heart is not at this point altered in position. The fluid is sharply demarcated from the heart by a shadowed area, the fluid being more easily lowered than the heart.

After removal of the fluid the heart is found to be in its normal position. The fluid limits are much larger than the heart limits, and, even in the extreme cases, the heart is not at this point altered in position. The fluid is sharply demarcated from the heart by a shadowed area, the fluid being more easily lowered than the heart.

The right border passes downward less diagonally than the left to meet the line of liver dulness at an obtuse angle. Attention was directed to the dulness in the fifth interspace to the right of the sternal edge by Rotch,<sup>16</sup> who considered it one of the earliest signs of pericarditis with effusion.

The lateral limits of dulness vary slightly with change in position. Similarly, the impulse may not be felt in the prone position, but palpable when the patient sits up and forward.

Pressure signs of the effusion are of considerable moment. Ewart<sup>17</sup> described a "first rib sign," *i. e.*, under these conditions the upper edge of the first rib can often be felt, due to the fact that the clavicle is raised, thus relaxing the ligament between the two bones. The liver and diaphragm may be considerably pushed downward. Calvert,<sup>18</sup> under the title "A New Sign Differential between Dilatation of the Heart and Pericarditis," published the result of his work which he believes shows that in pericarditis with effusion, the right lobe of the liver is low, varying in position from the fifth interspace to the sixth rib, while in dilatation of the heart, the lobe of the liver is high, in position from the fourth to the fifth rib.

The most striking signs of pressure are those due to compression of the lungs. Bamberger<sup>19</sup> first described a small quadrilateral patch of dulness low down in the intrascapular space on the left. Many authors have since called attention to the altered physical signs in this region. In my experience changes are nearly uniformly found near the inferior angle of the scapula on the left in cases of massive effusion in the pericardium. The most constant sign is dulness of varying degree, usually marked, sometimes accompanied by diminished fremitus and respiration and at others by a more or less intense bronchial type with increased voice sounds. Rarely bronchophony or egophony is present. In a few instances I have been able to demonstrate a considerable lessening of the above signs when the patient leaned forward in a sitting position. These signs just described are sometimes so striking as to lead to a diagnosis of pneumonia.

#### CHRONIC ADHESIVE PERICARDITIS.

This sequel of acute inflammation of the pericardium is by no means rare but so frequently escapes detection that it is not given deserved prominence among the forms of pericarditis. Pitt<sup>20</sup> states that among 10,000 post-mortem examinations at Guy's Hospital he found 400 cases of acute pericarditis and about the same number of the adherent form of which one-sixth showed universal adhesions. Smith<sup>21</sup> found among 3,053 autopsies at the Massachusetts General Hospital (1897-1913) complete or partial obliteration of the pericardium in 62. In my own series of 3,683 autopsies partial or complete obliteration of the pericardium sac was

found in 32 instances among the acute cases, or 21%, and in 96 of the chronic cases, or 46%.

The picture of adherent pericarditis is quite as varied as the degree and nature of the anatomic changes, and with few exceptions is an indefinite one. It may present a considerable variety of phenomena or none, according to the degree of disturbance of the circulation and respiration.

Laennec<sup>22</sup> records his observation that "adhesion of the heart to the pericardium frequently does not interfere with the exercise of its function." The accuracy of his conclusions has been established by many clinicians since Laennec's time. If the adhesions be confined to the heart and its enveloping sac, even though the fusion between the serous surfaces is complete, the embarrassment to this organ is trifling and does not lead to hypertrophy or dilatation. It is only when the pericardium becomes glued to adjacent structures, either posteriorly to the mediastinum, anteriorly to the chest wall or below to the diaphragm and therefore more or less fixed ("Symphyse pericardique," "chronic mediastino-pericarditis") that the movement of the heart is impaired. The resulting disturbances are purely mechanical and affect the heart, the venous circulation and the respiration. All symptoms and signs are directly referable to this "impediment to the passage of blood through and out of the heart" and to the interference with respiration during inspiration.

Pitt<sup>23</sup> suggests that the resulting interference with movement, size and efficiency of the heart, probably depends on whether the heart remains dilated a sufficient time to permit adhesions to become firm, in which case it can never contract. If, on the other hand, the heart adjusts itself while the adhesions are soft, permanent impairment need not result. Later, when the adhesions are firm and fibrous, the pericardium may be so completely fixed as to prevent subsequent dilatation. The exact mechanism by which the above mentioned results are brought about has been ably discussed by Keith,<sup>24</sup> Wenckebach,<sup>25</sup> and others.

Pick,<sup>26</sup> in 1896, described a form of adherent pericarditis accompanied by cirrhosis of the liver, extreme ascites without jaundice, and oedema of the legs, which is often mistaken for hepatic cirrhosis and to which he gave the term "pericardial pseudo-cirrhosis of the liver." Cases of so-called "multiple," "poly-serositis," or "polyorrhomenitis," probably form a part of this same general group.

All cases of adherent pericarditis then fall roughly into one of three groups: first, those of simple fusion between the serous surfaces of the pericardium and which are usually without characteristic signs or symptoms and therefore seldom recognized clinically; second, those cases with adhesions of the pericardium internally and externally, the clinical picture of which is that of cardiac and respiratory failure; third, those cases of extensive intra- and extra-peri-

cardial adhesions and also evidences of extensive general involvement of other serous surfaces.

Regarding the symptoms of adherent pericardium little need be said. They are essentially those due to respiratory embarrassment and to cardiac insufficiency. Cyanosis and dyspnoea are usually present in all severe cases. Orthopnoea is often seen. Pain is rare. General oedema sometimes occurs in the severest forms.

#### PHYSICAL SIGNS OF ADHERENT PERICARDIUM.

Although a considerable list of signs can be mentioned none are constant or if present, strictly pathognomonic. Practically all are, as in the case of the symptoms, the direct result of fixation of the intrathoracic structures, especially the heart; and therefore concerned especially with the circulation and respiration.

Depression of the chest wall over the whole or a portion of the precordial area may be seen, less commonly a moderate degree of bulging. Neither condition can be considered as characteristic of this form of pericarditis, however. The position of the apex beat is to a varying degree fixed, and Achelis<sup>27</sup> considers this defective displacement with change in position or respiration, of the first significance diagnostically. It is frequently considerably displaced outward as is characteristic of cardiac dilatation. More commonly than otherwise, it is raised, being palpable only in the third and fourth spaces, rarely also in the second. Marked variation in the nature, force and area over which the cardiac impulse is felt is also common.

Among the most trustworthy signs, if the heart be adherent to the anterior chest wall, is the retraction of the intercostal spaces with ventricular systole, usually most striking in the area of maximum impulse but often also over more or less of the entire precordia. Less constantly a systolic recession is to be observed in the epigastrium resulting from extensive adhesions between the pericardium and diaphragm. With the patient in a sitting position a common phenomenon is a retraction of the lower ribs in the left posterior and lateral aspects of the thorax, "Broadbent's sign." Broadbent<sup>28</sup> explains this as resulting from the upward displacement of the diaphragm with each systole of the heart, which pulls the false ribs inward. Rarely this sign has been observed by this author and others to be present with a greatly enlarged heart, but in such cases the movement varies with respiration, which never occurs when due to adhesions of the pericardium (McKenzie). In my experience, this sign, when present, is one of the most distinctive of adherent pericardium. Bramwell<sup>29</sup> regards the diastolic rebound or shock, often over the chest wall in the region of the palpable impulse, as highly characteristic. Similarly a systolic impulse may in rare cases be heard or felt posteriorly.

One of the most commonly described signs is

the so-called "pulsus paradoxus," "pulsus inspirationis intermittens" or "Kussmaul's sign," that is, a variation in the pulse associated with respiration, the rate becoming slower and the force less with inspiration. The sign occurs in other conditions as well, and is by no means constant or definite in this form of pericarditis and therefore is of doubtful value.

Kussmaul<sup>30</sup> has called attention to the swelling in the cervical veins synchronous with inspiration, which he explains as due to the fact that the adherent pericardium prevents the dilatation of the right ventricle, which normally occurs during the first part of respiration. Sudden diastolic collapse of the jugular vein was described by Friedrich<sup>31</sup> and considered by him an important sign.

Auscultation yields nothing worthy of special mention. If the union of the visceral and parietal pericardial surfaces is not universal, a rub may be present. Betz<sup>32</sup> has described a "peculiar blowing or whistling systolic sound" which he regards as characteristic of adhesions of the pericardium to adjacent tissue.

#### X-RAY EXAMINATION.

It is hardly possible to emphasize too strongly the importance of an x-ray examination in the diagnosis and differential diagnosis of pericarditis. In all forms of inflammation of the pericardium with fluid exudate or adhesions, it furnishes in many instances more reliable data than either the symptoms or signs. It is true, however, as with other intrathoracic conditions, that the diagnosis should never be made on the x-ray findings alone, but only when these are considered together with the clinical symptoms and signs. There seems to be a general agreement among writers on the subject that the normal pericardium cannot be differentiated from the heart shadow, but Rönfeldt, after a careful study of a large series of cases, concludes that the normal can be made out in about one third.

Simple fibrinous changes in the pericardium give no positive x-ray findings. With small effusions into the pericardium the x-ray examination likewise furnishes no aid to diagnosis, but with larger amounts of fluid, certain features make the form of the heart shadow quite distinctive. With few exceptions, the outline of the shadow of the distended pericardium in the roentgenogram corresponds fairly closely to the area of dullness mapped out by percussion. The shadow is large, the outline rounded, or more or less triangular in shape, depending on the amount of fluid. Its broad base is directed often reaching the outer limits of the thorax on the left, and from there to the middle of the sternum on the right, or the middle of the sternum on the right, and the rounded apex is directed toward the cardiac angle, often overlapping the heart shadow so commonly seen in pericarditis. The shadow, except in the case of small effusions, is not triangular in this position. In the lateral position the angle is a right angle, the apex directed toward the cardiac angle, and the base is directed toward the middle of the sternum.

greatly diminished or entirely effaced. The shape of the area varies significantly with changes in position. In contrast to the shadow of an enlarged heart, the pulsation usually observed at the left border is absent. Wessler<sup>34</sup> thinks this may also be the case in dilated heart. Above, the shadow is somewhat raised and encroaches on the great vessels at the base of the heart. In the upper one-third of the left border there is commonly a varying degree of concavity of the outline on the left, corresponding to the so-called "Sibson's notch." If combined with adhesions within the pericardium the outline of the distended sac may not be uniform and even marked bulging, especially to the left, is rarely seen (Wessler).

The x-ray appearances in adherent pericardium have been the subject of much careful investigation by Lehmann and Schmoll<sup>35</sup> Achelis,<sup>36</sup> Tornai,<sup>37</sup> Vaquez and Bordet,<sup>38</sup> and others, and the essential features appear to be well established. Much of a rather technical nature has been written, especially by the above observers, regarding the methods of x-ray examination, which does not fall within the scope of this paper. Uncomplicated obliterative pericarditis cannot be certainly demonstrated by roentgenograms.

The practical conclusions of the above authors as to the characteristics of adherent pericardium in roentgenograms may be summarized as follows:

1. With adhesions of the pericardium to the anterior wall of the thorax, the clear space between these two structures is much diminished or obliterated where an x-ray examination is made in the oblique or lateral position. Achelis urges caution in drawing too definite conclusions from such findings, as this obliteration may be present in the case of extreme cardiac hypertrophy.

2. The outer limits of the shadow laterally do not appear smooth and clear as in hypertrophy or dilatation of the heart, but are vague and indefinite and frequently with notched or tooth-like outline due to adhesions.

3. The normal angle on either side between the pericardium and diaphragm is sometimes completely filled in by adhesions.

4. An indistinct or obliterated heart pulsation is seen.

5. Various modifications in the displacement shadow of the heart, with respiration and change of body position, are also characteristic.

6. The diaphragm shows varying degrees of immobility during respiration.

7. In the lateral position a posterior mediastinal pericarditis is shown by obliteration of the normal triangular clear space.

#### PARACENTESIS PERICARDII.

Whether for diagnosis or for therapeutic purposes aspiration of the pericardium is a procedure altogether too little known. During the past ten years many authors have urged the

more frequent employment of paracentesis in pericardial effusions and in consequence it is now unquestionably much more often done than formerly.

Considering the relative frequency of pericarditis, and its favorable course with spontaneous recovery in many instances, it must be admitted that paracentesis is rarely necessary. It is indicated when the amount of effusion is so great as to give extreme embarrassment of the respiration and circulation and thus endanger life, or when a large effusion shows no tendency to absorption. In occasional cases it is important to establish the nature of the effusion, especially when a purulent exudate is suspected. Sears<sup>39</sup> has emphasized the importance of exploratory puncture in all suspected cases of this type, urging the advantage of early radical treatment of pyopericardium on the same grounds as of pus in the pleural cavity. The favorable results of surgical treatment by pericardiotomy during recent years offers a weighty argument for early aspiration for diagnosis.

Puncture of the pericardium is far less simple than of either the pleural or peritoneal cavities and is by no means free from dangers. A dry tap is not infrequent even when a considerable amount of fluid is present,—a failure which is explained by the fact that adhesions binding the heart to the pericardium may make it difficult to reach the fluid or because the exudate is apt to contain a large amount of fibrin with which the needle may become plugged. The x-ray examination is often of great value in indicating the position of the fluid in the pericardial sac.

The possible untoward results of paracentesis of the pericardium are several. A few cases are on record of sudden collapse and death immediately following it. The dangers of infecting the pericardium are but slight and can be disregarded if strict attention be given to asepsis. An ever present possibility is the puncture of the pleura and infection of this cavity if the pericardial exudate is purulent. The gravest complication but, fortunately, a rather rare one, is the wounding of the heart, leading to fatal haemorrhage. Boxwell<sup>40</sup> reports such a case where the ventricle and auricle were punctured and death resulted from hemorrhage. The dangers from this cause seem to be not so much from puncture as of tearing of the heart muscle by movement of the heart over the end of the needle.

The question of the best site for aspiration is a matter of wide difference of opinion and a great variety of points have been recommended. From the work of Zinn,<sup>41</sup> Blehmman,<sup>42</sup> Schaposchenko and Damsch,<sup>43</sup> and others, it is clear that the least amount of the effusion collects in front of the heart, the bulk of the fluid being in the posterior and left dependent portions of the pericardium. The right side of the diaphragm meets resistance from the liver and cannot be pressed down as on the left, where the resistance is less, and therefore the accumula-

Note particularly the characteristic obliteration of the acute cardio-hepatic angle on right.

tion of exudate in the right lower part of the pericardium is usually small in comparison. This would seem sufficient reason for not choosing the fifth right intercostal space (Roth's Point) as the site for paracentesis. Likewise for the same reason the various points to the left of the sternal border, either inside or outside the internal mammary artery, are unsuitable. Furthermore, the dangers of wounding the heart are greatly increased in this region.

The region most commonly chosen (Curschmann, Zinn, West, Sears, and many others) is the fifth or sixth interspace, 2-3 cm. outside the nipple line and inside the outer limits of dullness. The position is one of the most favorable for drainage of the pericardium and the chances of injury to the heart very slight. The needle introduced at this point may transfix the pleura, but this accident is of little or no importance.

One other point of puncture has come much in favor of late, namely, the sub-xiphoid of Marfan.<sup>44</sup> The advantages of this method as stated by Marfan are as follows. 1. The distended pericardial sac lies very close to the xiphoid and is very easily entered; 2. The sac is punctured at its lowest part and can therefore be more easily and completely drained; 3. There is no danger or injury to the heart; and 4. There is no possibility of entering the pleural cavity. Blechmann<sup>45</sup> and Rieux<sup>46</sup> believe this to be the most satisfactory and safest method.

## A SECOND NOTE ON THE FREQUENCY OF EPILEPSY IN THE OFFSPRING OF EPILEPTICS.

By D. A. THOM, M.D.,

Monson State Hospital, Palmer, Mass.

SINCE publishing my early investigations concerning the Frequency of Epilepsy in the Offspring of Epileptics,<sup>1</sup> it has been my privilege to have the aid of a social worker to check up the results of my previous work. The fact that in only 8 of the 138 matings, where one or both parents were epileptic, did the offspring develop epilepsy was indeed surprising. Yet, when the ancestors of this same group were studied with the same point in view, direct similar heredity there again were only eight cases, or 5.8%. But, as I explained in my previous article, the data I obtained were largely through correspondence and personal interviews with friends and relatives of the patients and, therefore, subject to many sources of error; and had they not diverged so widely from the only other similar research work, that of Ebbverla, I should have hardly considered them worthy of publication.

The following table will show at a glance what a marked difference results when I

	Frequency	Percentage	Frequency	Percentage
Ebbverla	139	6.2	71	5.1
Thom	138	6.8	79	5.8

That 273 offspring out of a total of 533, or over 51%, should have developed epilepsy, seemed more startling to me than my own figures of only 10 epileptics in my total of 553 offspring, or less than 2%.

My purpose has been to make a more intensive study of the cases already reviewed, to determine, if possible, to what extent epilepsy is transmitted directly from parent to offspring. The 33 cases I wish to report include 7 of the 8 matings where the resulting offspring were epileptic, and the total of 10 epileptic children include 8 of those reported in my last paper. In other words, the field worker uncovered two more cases of epilepsy in her more exacting study of these 33 cases than I did by my less accurate method. Of these 33 cases, 13 were male and 20 female. Thirteen cases, including 11 females and two males, had their epilepsy before marriage; 19 cases, 11 males and 8 females, had their first convulsions after marriage. The 33 matings resulted in 133 offspring, 86 of whom are living and 47 are dead. Of the total of 133 offspring, there is a history of convulsions in 10, five having died in infancy during seizures, two becoming arrested cases and three confirmed epileptics.

The causes of death in the cases of the deceased were as follows:

Infantile convulsions	5
Diphtheria	5
Tuberculosis	5
Indigestion	5
Malnutrition	2
Scarlet Fever	1
Purpura	1
Menigitis	1
Unknown	9
Unascertained	13

47

The present age of the surviving children is as follows:

Under 1 year	1
Between 1 and 5 years	10
" 5 " 10 "	14
" 10 " 15 "	10
" 15 " 20 "	11
Over 20 years	40

86

This group of living offspring whose parents, one or both, were epileptic contains 46 cases still under 20 years of age, and in the epileptic zone. What per cent. of these cases will develop epilepsy no one can say at this time, but it is not probable that it will be 50%. Of the cases over 20 years of age, heredity will play a much less important part. So it appears that the results of the earlier work have been to a large degree substantiated by this more intensive study, and that the conclusion that epilepsy is less often transmitted directly from parent to offspring than we have heretofore been led to believe is justified.

## ARTIFICIAL HELIOTHERAPY: THE MERCURY-VAPOR-QUARTZ LIGHT A VALUABLE THERAPEUTIC AGENT.

By JOHN BRYANT, M.D., BOSTON.

Is sunlight or is heliotherapy of real value in medicine? This question has been pretty conclusively answered in the affirmative. It appears that the live agent or active principle in producing the good results is the action of the blue rays in producing a pigmentation of the skin, the pigment then in some manner becoming a circulating metabolic rectifier; thus in Switzerland it has been noted that tubercular patients recovered, and that their prognosis varied with the rapidity and ease of pigmentation of their skins.

If blue light is the active agent, it follows that any method which delivers blue light to the skin is a valuable substitute for heliotherapy, the more so as any electrical method is always available, whereas the sun, at most, is available only at certain hours, even when not obscured by smoke, fog, or clouds.

It is known that the mercury-vapor are generates plenty of short-length actinic rays. It is also known that quartz is a substance, and one of the very few, not opaque to the blue rays. It is, therefore, theoretically possible to produce a light which will deliver at the skin blue light not associated with excessive heat. At least one such lamp has been for some time available.

To produce pigmentation is to reproduce the effect and to promise the results of which actual sunlight is capable. The only question remaining, therefore, before being forced to admit the value of such a lamp, is whether it really does produce in action a rapid pigmentation of the skin exposed to its rays.

One of the lamps in question has been in use in my office since mid-August. Employed in connection with graduated heat from incandescent carbon filaments, as a metabolic stimulant for asthenic chronic intestinal cases, it has been clearly demonstrated that the light of this lamp actually does produce very rapidly a redness, even to blistering and peeling of the skin, and soon results in the acquisition of a pigmentation of the skin not to be distinguished from that obtained by much longer exposure to actual sunlight.

The lamp is, in fact, so active that a five-minute exposure at a distance of a metre or so may result in a sensitive skin turning, as one patient expressed it, "as red as a lobster," by the end of twenty-four hours.

Since many patients will find it not only more convenient, but actually a saving of time, to have their skins tanned by artificial heliotherapy, in a quiet room, regardless of the time of day or night, and since it is proved that the lamp does produce the all-important pigmenta-

tion, it is suggested that the use of such an apparatus might to great advantage become more general, not only in private practice, but in hospital circles. Used rightly, such a lamp is certainly a powerful and valuable addition to therapeutic resources, as an easily available and ever ready substitute for actual heliotherapy. Its indications would seem to be those of sunlight itself.

## Therapeutic and Preventive Medicine.

### THE TREATMENT OF OBESITY BY A RATIONAL DIET.

BY EDWARD E. CORNWALL, M.D., BROOKLYN, N. Y.

*Attending Physician to the Williamsburgh and Norwegian Hospitals; Consulting Physician to the Bethany Deaconesses Hospital.*

In the treatment of obesity, the object aimed at is the combustion of a definite amount of surplus fat in the body, and the prevention of its reaccumulation. Regulation of the diet constitutes the essential part of this treatment.

It would be an easy matter to calculate the formula for reducing the fuel value of the food intake, if oxidation in the body were always regular and uniform. In such case the amount of reduction would have a caloric value, equal to that of the quantity of body fat which it is desired to burn up. For example, if the reduction in weight desired is at the rate of two pounds a week, which means the combustion daily of about four and a half ounces of body fat, the fuel value of the daily ration would have to be reduced about 1000 calories below the normal for size, age and activity. But the oxidation of fat in the body is not always regular and uniform, and does not always respond promptly and fully to the demands made on it by partial starvation. Extensive variation of this oxidation in different individuals is a matter of common observation: frequently small eaters are seen to remain persistently stout, while large eaters are persistently remain thin. Nevertheless, the formula suggested serves as a basis on which to work out the best formula for the individual case.

Measures to improve oxidation in the body are called for in the treatment of obesity; and as all metabolic processes are more or less under control of the internal secretions, such measures are directed very properly toward improving the condition or action of the glands which produce those secretions. This means, as regards diet, regulation of the quality as well as quantity of the food, so as to diminish, in particular, the toxemias of alimentary origin which could injure those glands or disturb their functions. This is effected mainly by restriction or exclu-

sion of articles of food of animal origin excepting milk and its products.

The following practical suggestions for regulating the diet in obesity seem in harmony with the facts and principles above alluded to.

Bear in mind that regulation of the diet is the principal thing in the treatment of obesity, and that this regulation should be qualitative as well as quantitative.

Insist on scales and measures being used to secure accuracy in carrying out the dietetic prescriptions.

Do not rely for protein chiefly on animal tissues and eggs, as is done in most obesity diets, but secure protein chiefly from milk and its products, which supply all the different amino acids needed by the body and are relatively easy of metabolism, being free from purins and comparatively insusceptible to putrefactive processes in the alimentary canal. If no other morbid condition is obviously present, a small amount of animal tissues or eggs may be included in the diet; but in cases complicated by obvious insufficiency of nitrogenous metabolism (as shown by gout, gravel, migraine, arteriosclerosis, chronic nephritis or hepatic insufficiency), or by disease of the alimentary canal, which increases the habitual production in that canal of putrefactive poisons and their absorption therefrom, the amount of flesh and eggs should be very small indeed or they should be excluded altogether. Such qualitative regulation of the protein ration for the special purpose of easing the burden of nitrogenous metabolism, is a cardinal principle in this method of treating obesity and its distinguishing feature.

Include plenty of fresh fruits and vegetables in the diet, in order to supply full rations of the body salts and vitamins; but use careful selection so as to include only fruits and vegetables which are comparatively free from objectionable qualities, such as indigestibility, possession of purin or oxalic acid content, and offensiveness to the patient's idiosyncrasies.

Allow water to be drunk in ordinary quantities.

Begin the treatment by restricting the fuel ration so as to supply about 1000 calories less than the minimum health ration for the particular patient.

Do not reduce the quantity of protein much below the minimum health ration, but let the loss fall chiefly on the fat and carbohydrate.

Do not, as a rule, try to reduce the weight by more than two pounds a week, on the average. Such a moderate reduction is not often attended with any unpleasant consequences.

Bear in mind the exceptions which exist in regard to reducing weight: be cautious in reducing the weight of those afflicted with serious diseases; relax the rigidity of the diet or discontinue all attempts at reduction, if in the course of treatment symptoms of distress or weakness

appear (which does not often happen with this plan of treatment); and do not, as a rule, attempt to reduce the weight of those entering on old age who have been obese for a considerable time.

In most cases allow occasional periods of rest from the rigid diet, and while giving the minimum health rations, take note if the weight increases in consequence.

A series of dietetic prescriptions for obesity, devised by the writer in accordance with the above suggestions, have the food values shown in the index table given below. These prescriptions readily lend themselves to modifications for individual needs. The numbers in the main column of protein values refer to protein derived from milk, cereals, fruits and vegetables; and the numbers after the plus signs in the same column refer to protein derived from animal tissues and eggs. It will be seen that the protein derived from the latter sources is greatly restricted in this plan of treatment.

INDEX OF OBESITY DIETS.

Prescription Number	Protein grams	Fat grams	Carbohydrate grams	Calories
I	50	32	112	975
II	50+4	36	113	1000
III	50+14	41	113	1100
IV	58	40	125	1125
V	58+4	42	125	1150
VI	60	44	136	1250
VII	62+14	48	125	1275
VIII	65+14	52	140	1375
IX	76	51	170	1400
X	76+14	58	170	1525

### Clinical Department.

#### THE STREPTOCOCCUS MUCOSUS CAPSULATUS AS A CAUSE OF MASTOID DISEASE.\*

By GORHAM BACON, M.D., F.A.C.S., NEW YORK.

Professor of Otolaryngology, College of Physicians and Surgeons, Columbia University, New York.

ACCORDING to my experience the streptococcus mucosus capsulatus is the most insidious and destructive germ with which the otologist has to contend, and the question of an operation, when the mastoid cells are involved, is a most important one.

In 1905 Dr. George Sloan Dixon published in the *Archives of Otolaryngology*, Vol. xxiv, Part 6, a paper entitled "Report of a Case of Panotitis Resulting in Meningitis, with Pathological Findings," in which he reported the case of a nurse who was under my care in the New York Eye and Ear Infirmary. She entered the hospital on February 7, 1904, and gave a history of an acute

attack of otitis media which had begun six weeks previously. She had labyrinthine symptoms which, with the knowledge we have today, would have warranted an operation. There was no mastoid tenderness. On the fourth day after admission meningitis developed, and she died almost immediately.

In this paper Dixon says: "This case seemed to call for an examination of my bacteriological examinations during the past four years. They were found to comprise about 1050 cases of acute and chronic purulent otitis, with and without mastoiditis; 2.75% of the infections were Friedlander's pneumococcus, or, more properly, the bacillus mucosus capsulatus." Of 30 cases due to the bacillus mucosus capsulatus, 15 had existed for 42 days or over, before operation. Of these, two had perisinous abscesses with Bezold perforation; one had perisinous abscesses and cortical perforation with subperiosteal abscess; four had epidural abscess (one of which died of meningitis); one had panotitis and died of meningitis; and one had brain abscess and also died. Six cases had periosteal abscesses.

Dixon further says: "Of those cases which had existed under 42 days, four promptly recovered after paracentesis, but mastoid operation was required on the remaining ten, and all did well except one patient who died of pneumonia."

Such a report only emphasizes the virulence of this germ, and since that time I have taken particular pains to watch these cases most carefully, especially with reference to an early operation.

During the years 1914-1915, I had the four following cases in private practice:

CASE 1 was that of Caroline R., aged 5, who was seen by me in consultation on May 12th. She had had lobar pneumonia one month before when both ears had been affected, and there had also been an acute inflammation of the throat and enlarged glands in the neck. The right ear had cleared up, but the left had been discharging for about three weeks. The left membrane had ruptured spontaneously two weeks before I saw her. There was slight tenderness over the mastoid tip, the temperature had been rising, a little higher each day, from 99.2° in the morning to 101 or 102 in the afternoon, and a culture showed that the streptococcus mucosus capsulatus was the cause of the infection. A simple mastoid operation was performed that same day at the Infirmary. As soon as the tip was opened pus poured out. There was a very large cavity and the whole mastoid cells were involved; softened bone and granulations were everywhere. The wound was dressed in the usual way and the child made an uneventful recovery. Her temperature was 99° before the operation.

CASE 2 was that of S. L. P., aged 64, who came to me on April 15th, complaining of pain in the right ear, and giving a history of a feeling of fullness in that ear three days ago. Examination showed the membrane slightly red and swollen about the short process as well as the canal. There was also slight tenderness on pressure over the mastoid. He was given drops to use, but as the pain was not relieved,

\* Read at the annual meeting of the American Otological Society held in Washington, D. C., May, 1916.

I opened the drum membrane under gas that same evening. Some serous fluid and gas escaped. He was then directed to douche the ear frequently during the day. The pain seemed to yield to treatment, and he was apparently doing well until three days later when the ear stopped discharging and began to pain again. The patient felt very dizzy and almost fainted on attempting to rise on the morning of April 19th, and that afternoon the drum membrane was again incised under gas. On the 20th the ear was discharging freely and there was practically no dizziness. An x-ray picture showed cloudiness of the mastoid cells on the right side, and a culture showed the cause of the infection to be the streptococcus mucosus capsulatus.

The ear discharged very freely until April 22d, when the perforation closed. On the 24th the patient felt very much better after the best night he had had for a long time, and the drum membrane seemed to be clearing. On the 26th of April it became necessary to open the drum for the third time. On the 29th there had been but a slight discharge, and the patient seemed to be in about the same condition as he was ten days before. A second x-ray plate showed a slight increase of cloudiness on the affected side.

A consultation with Dr. Lewis and Dr. Townsend was held, and Dr. Lewis and I strongly advised operation, which was done at the New York Eye and Ear Infirmary on April 30th. The usual incision was made. The bone of the outer cortex was extremely hard and very thick. The large tip cell was filled with pus and granulations, and the rest of the mastoid contained granulations and softened bone and some pus. The antrum was large. Everything was cleaned out and the wound packed with sterile gauze. The patient left the hospital in a little less than two weeks, and his recovery was steady though a little slow. The wound was dressed in the usual way, and gradually filled up. By June 11th there was one spot of bone still uncovered near the tip and there was a small sinus at the tip leading into the soft tissues. That morning the patient came into my office with marked swelling, extending down into the neck, which had come on suddenly the night before. This seemed to be caused by about a half teaspoonful of pus which I squeezed out of the same sinus, and by the next day the swelling had practically subsided except around the tip.

The patient went away for the summer and was under the care of a local physician. He had been very much run down, and this was undoubtedly the cause of the slow healing of the wound. The change of air to the country greatly improved his general health, and on his return to the city the wound was entirely healed and had been so for about a month.

CASE 3 was that of J. W. A., who has been a patient of mine for a number of years, suffering from a chronic middle-ear catarrh on both sides, and exostoses in each auditory canal. On December 20th I was called to see him by his family physician, as he had a severe cold and pain in the right ear. On examination I found some vesicles filled with blood in the canal, which prevented a good view of the drum membrane. He was directed to syringe the ear every two hours with a solution of boric acid. The next afternoon, as the temperature suddenly went to 101° after being normal in the morning, and as there was some tenderness over the lower

third of the mastoid bone, especially at the tip, I incised the drum under gas. After the incision the temperature was normal, but the discharge became more profuse and purulent and the tenderness over the mastoid was quite marked, especially over the tip. A culture was made and showed that the streptococcus mucosus capsulatus was the cause of the infection. A blood count showed the polys as high as 78%, and the leucocytes ranging from 5000 to 6000.

An operation was performed at the New York Eye and Ear Infirmary on December 25th. The usual incision was made. Pus was found under pressure in a large cell in the lower third of the mastoid. The outer cortex was very hard, especially over the antrum. A very large antrum was filled with soft bone and many granulations. The dura was uncovered to a very small extent in the middle fossa. The wound was packed with iodoform gauze in the upper part, over the dura, and with plain gauze in the lower part.

The patient left the hospital on January 5th, and the wound was dressed in the usual way. He was considerably prostrated by the infection which seemed to pull him down very much, and as a result the wound was slow in healing. By the first of March it was practically healed and the patient went South. He returned the first of April, greatly improved in his general health and with the wound in excellent condition. The hearing of the right ear is practically the same as that of the left, though that of both is somewhat impaired, owing to his old catarrhal trouble.

It is interesting to note, in connection with this case, that a urinalysis, made just before the operation, showed the presence of some albumin and a few casts evidently due to the poison, as an analysis made a month previously showed no abnormal conditions.

CASE 4 is that of Paul B., a medical student, who was seen by me in Roosevelt Hospital in 1914. He had an acute inflammation of the ear which was due to the presence of the streptococcus mucosus capsulatus. The ear had discharged spontaneously before I saw him, and there was slight tenderness over the mastoid bone. Five x-ray plates were taken of the mastoid bone. The first three plates were cloudy but the fourth showed a less cloudy appearance and the final one was so much cleared up that I decided not to operate, as the drumhead had resumed its normal appearance and all tenderness on pressure over the bone had disappeared.

The following cases are a few of those treated in my clinic at the New York Eye and Ear Infirmary during 1913, 1914 and 1915:

CASE 1. Barney G., a Russian, aged 53 years, came to the Infirmary on May 31, 1913, and gave the following history: Pain in the right ear began six weeks ago, following a cold. He suffered pain every night for over four weeks, and two weeks ago noticed a slight purulent discharge which has continued up to the present time. The drum membrane was incised in the clinic, and on the next day a post-auricular swelling appeared and gradually increased in size. Examination showed slight discharge from the right ear, the superior wall sagging, the drum membrane red and bulging, and a perforation in the lower part. There was tenderness on pressure over the mastoid area, especially over the

antrum. A culture was made and found to be the streptococcus mucosus capsulatus. An x-ray plate showed the left mastoid clear, with large pneumatic cells. The right seemed to be completely disorganized; two localities suggested perisinous and epidural abscesses,—the former below and the latter near the knee of the sinus. Three days after admission to the hospital a simple mastoid operation was performed and soft pneumatic cells were found with large perisinous and epidural abscesses. The tip was also removed. The temperature on admission was 99.2°; after the operation it rose to 101.6° but gradually came down to normal. The patient was discharged from the hospital on June 14th, and the subsequent dressings were done in the out-patient department.

CASE 2. Thomas D. Irish, aged 55 years, was admitted to the Infirmary on October 21, 1913. His illness began on August 15th, with a severe attack of pain in the left ear which continued until the drum ruptured, twenty-four hours later. Following that there was intermittent discharge and occasional attacks of pain, none of which was severe, and he was advised to come into the hospital because of the discharge and tenderness over the mastoid. A bacteriological examination showed the streptococcus mucosus capsulatus. The x-ray showed the right mastoid with moderate-sized cells of the pneumatic type; the cells were clear. The left mastoid seemed to be similar, but very cloudy. The sinus was far forward and looked as though it might be under the canal. A simple mastoid operation was done October 21st, revealing a large perisinous and epidural abscess, and a mass of dark necrotic granulations filling the antrum. The dura under the middle fossa was exposed and the sigmoid sinus for a considerable space. The temperature was 96.2° on admission, and immediately after the operation went to 101°, fluctuating between that point and 98° for four days until it became normal. The patient was discharged from the hospital on November 6th, and after that was dressed in the out-patient department.

CASE 3. Fred G., an American, aged 21, was admitted to the hospital July 25, 1913. He gave a history of pain and deafness in the right ear on July 7th, following sea bathing. The drum membrane ruptured and he came to the clinic the next day with a profuse discharge from the ear. He was admitted to the hospital for observation and the drum membrane was freely incised. There was slight sagging of the posterior wall and moderate pain. Examination of a smear showed strong suspicion of a streptococcus mucosus capsulatus, but Dr. Dixon could not be sure of it. The x-ray showed a moderate-sized pneumatic mastoid left, with extensive development of zygomatic cells, all of which were clear. The right side was cloudy throughout. The sinus seemed superficial and there were perisinous and epidural abscesses. The usual operation was performed on the right ear on July 31st. The bone was of the large pneumatic cell type filled with soft necrotic granulations. A large extent of dura was exposed, and the sinus was exposed and healthy. The tip and zygomatic cells were carefully cleaned out. The patient was discharged on August 8th, and treated afterward in the clinic.

CASE 4. Rose K., a Russian, aged 21, was admitted to the hospital on September 2, 1913, with a history of pain in the left ear five weeks before, fol-

lowing a cold. The drum had been incised one week before, and since then there had been a slight purulent discharge. Pain had been severe for the past few days with pain behind the auricle. Examination showed the left ear filled with thick pus. The drum membrane was bulging and perforated with sagging of the posterior superior wall, and there was slight tenderness on pressure over the mastoid antrum and tip. A bacteriological examination showed the cause of the infection to be the streptococcus mucosus capsulatus. The x-ray showed the right to be a moderate-sized clear pneumatic mastoid, with a number of zygomatic cells. The left was of the same type, but very cloudy throughout. Operation was advised, but refused, and the patient left the hospital on September 7th.

She came to the Infirmary again on September 13th, and on the 16th a simple mastoid operation was done on the left ear. The outer cortex was rather thick, and the bone was of the moderate-sized pneumatic type. There was no free pus. There were necrotic granulations and the bone was broken down. The zygomatic cells were cleared out and the tip was removed, and a small area of dura in the antrum and middle fossa was exposed. The patient was discharged on October 2, 1913, and treated afterwards in the clinic.

CASE 5. Adolph R., a Roumanian, aged 59, came to the Infirmary on June 3, 1913. His trouble began three months before, following exposure to cold. He had pain in the left ear for the first eight days and then had no further trouble, except an occasional rumbling noise, until two days before he came to the clinic, when the pain recommenced with a discharge. Examination showed a slight foul discharge from the canal, the membrane red and bulging, with slight sagging of the posterior and upper canal wall. There was no mastoid tenderness. The patient had diabetes. The bacteriological examination showed that the infection was due to the streptococcus mucosus capsulatus. A blood count showed the white cells, 7100, and the polys 61%. The x-ray showed the right mastoid to contain large pneumatic cells. The left was of the same type but cloudy throughout, disorganized below and behind, and probably an epidural abscess near the knee. There were high zygomatic cells. A simple mastoidectomy was done. There was very extensive destruction of the cells, pus in the antrum and tip, and both an epidural and a perisinous abscess found. The patient made a good recovery.

CASE 6. Jacob S., an American, aged 19, came to my clinic on November 19, 1912, with acute pain in the right ear of one week's standing. The membrane was red and bulging and was incised. The pain was relieved at once. There was little, if any, discharge. On December 30th, the patient noticed pain over the mastoid and the discharge increased in quantity. He came to the clinic again on January 5, 1913. Examination of the right ear showed a slight, thick discharge in the canal, which was constricted throughout and sagging in the posterior and upper portion. There was a small perforation in the drumhead, and slight tenderness over the mastoid antrum on firm pressure. The cause of the infection was the streptococcus mucosus capsulatus. An x-ray showed both mastoids to be of the large-celled pneumatic type, the right being hazy throughout, especially above and behind the antrum. The temperature was 98°. A simple mastoid operation

was performed and free pus was found in the antrum and tip. There was a perisinous abscess. The patient was discharged from the hospital on January 14th, and treated in the dispensary.

CASE 7. Christian S., a Greek, aged 30, came to the Infirmary on June 23, 1914, with a history of continuous and moderate discharge of one month's duration. He had had no severe pain. There was diffuse post-auricular tenderness and considerable sagging of the upper and posterior wall of the canal. The drum membrane was almost occluded. The bacteriological examination showed the streptococcus mucosus capsulatus. The x-ray examination showed a large clear-celled pneumatic mastoid on the right, and on the left the same type, but cloudy throughout. On operation an epidural abscess was found and a large area of dura was exposed. The sinus, covered with granulations, was also exposed. There was a very extensive and destructive process. The temperature was 99° on admission, and after the operation went to 100.3°. The patient was discharged on July 13th, and treated subsequently in the clinic.

CASE 8. Mary A., an Austrian, aged 36. Her illness began with severe pain in the left ear following a chill, four weeks before her admission to the hospital on September 8, 1914. The pain gradually increased in severity until the drum was opened. Her temperature on admission was 99.2°. The cause of the infection was the streptococcus mucosus capsulatus. Operation showed the diploetic type of bone. The entire process was extensively involved, and there was a perisinous abscess. There was no involvement of the posterior sinus cells. The tip was removed and a large area of dura was exposed. The patient left the hospital on September 17, 1914.

CASE 9. Max B., an Austrian, aged 32, was admitted to the Infirmary on May 18, 1915. He gave a history of pain in the left ear 10 days before. Two days after the pain began he came to the clinic and the drum was incised. Discharge continued until the day before his admission to the hospital when it ceased, and the pain began again. There was great tenderness on pressure over the tip, some constriction of the canal, and the drum membrane was swollen, reddened, congested and bulging. The bacteriological examination showed the presence of the streptococcus mucosus capsulatus. The x-ray plates showed a large mastoid, right, with extensive zygomatic cells. Cells were also present about the antrum. The left was a very large pneumatic mastoid, comparatively cloudy. The report from the laboratory characterized this as "probably an operative case." His temperature on admission was 101°. The operation revealed the cells filled with pus, and great destruction of the bone. The large tip cells were filled with pus under pressure. The sinus was covered with granulations forming a perisinous abscess. The patient left the hospital on May 28.

CASE 10. David D., a Scotchman, aged 68, came to the hospital on June 18, 1915. He first had pain in his left ear five weeks before. The drum was incised one week later and again three weeks after that. Two days after the last incision he developed severe pain in the ear and tenderness posterior to the auricle, and the discharge became more profuse. There was tip tenderness over the mastoid and a thick purulent discharge. A linear perfora-

tion was seen in the drum membrane. The laboratory reported the presence of the streptococcus mucosus capsulatus. The x-ray showed both mastoids of the pneumatic type with thick cortices. The right was fairly clear and the left quite cloudy. A simple mastoid operation was done on the left ear, and the mastoid cells were found filled with granulations and pus. The tip was completely removed. No sinus or dura was exposed. The temperature on admission was normal. The patient was discharged on June 30, and treated in the clinic.

CASE 11. Herbert F., an American, came to the clinic on March 4th, 1915, with a history of slight pain three weeks before. The ear had felt stopped up and deaf, and finally had ruptured spontaneously. Slight pressure over the tip caused pain. There was no sagging of the canal wall. The discharge was moderate. There was marked bulging of the drum membrane. A culture showed that the streptococcus mucosus capsulatus was the cause of the infection. The x-ray showed the right mastoid to be a moderate-sized clear pneumatic. The left was of the same type, but cloudy throughout. The usual mastoid operation was done. There was extensive involvement of the mastoid cells, which were filled with softened bone, granulations and thick pus. The temperature was 100 on admission.

From an analysis of these cases it will be seen that some patients complained of slight pain, and others of very severe pain, but that there was extensive destruction of the mastoid cells in all cases that came to operation, particularly in the hospital cases. There was both a perisinous and an epidural abscess in seven of the eleven hospital cases, and in two others the dura was exposed. In two of the private cases, also, the dura was exposed.

The x-ray is a most valuable aid in deciding upon the advisability of an operation. If a mastoid, which was previously shown to be cloudy, begins to clear up, and the symptoms show a steady improvement, I feel that we can afford to wait if the patient is carefully watched, and if a sufficient number of x-ray plates are taken. Such was the method pursued in the case of the patient who escaped operation. If, on the other hand, a patient is under treatment and the discharge persists while all tenderness on pressure over the bone has disappeared, it is more than likely that a destructive process is going on in the mastoid cells, and we are likely to find an exposed dura and sinus, particularly if the condition continues for from three to six weeks. A blood count is generally of little value.

In concluding, I desire to draw attention to the following points:

1. The patient may have very severe pain, or the pain may be slight, and the temperature is seldom much above normal.
2. Tenderness on pressure over the mastoid process may be well marked, or there may be none, especially where the outer cortex is thick.
3. The discharge in some cases is very profuse, while in others it is slight, and there may

or may not be sagging of the posterior and upper canal wall.

4. The x-ray is a most valuable aid, as the cells on the affected side will be cloudy, and in some instances it is possible to detect an epidural or perisinous abscess.

5. We should err on the safe side and operate when in doubt, for we often find a great destruction of bone, even in cases that present few symptoms. It is only in a few cases, which yield readily to treatment, that an operation can be avoided.

### A CASE OF DOUBLE EMPYEMA SUCCESSFULLY OPERATED UPON, WITH REMARKS UPON LOCALIZATION.

By F. B. LUND, M.D., and H. MORRISON, M.D., BOSTON.

This case of double empyema, is reported because of the rarity of double empyema,—at least of case reports thereof,—and because of the interest attached to the localization of the abscesses, which was quite different upon the two sides.

A girl of 16 was attacked on March 20, 1915, by epigastric pain, vomiting, headache, and slight cough. At Dr. Morrison's first visit her temperature was 102, pulse 120, and respiration 30. Examination showed signs of beginning consolidation at the base of the left lung. The following morning there were signs of frank consolidation of the left lower lobe.

From the very first, this patient looked very sick. On April 1st, her leucocyte count was only 5,000, showing her poor resistance. On April 2d,—the fourth day of the illness,—there was involvement of the right lower lobe; and by the end of the ninth day, the middle and lower lobes of the right lung and the lower lobe of the left were solid. The girl was obviously septic. Her leucocyte count had risen to 23,000. The temperature ranged from 100°-101° F., mornings, to 103°-104°, evenings. There was slight cyanosis, with considerable dyspnoea. The pulse was rapid; the systolic blood pressure was 115. Cardiac stimulation had been instituted early in the disease. There was considerable cough, and the sputum was muco-purulent and very tenacious.

The expected crisis failed to appear during the next six days. The patient was prostrated; she was running a septic temperature and was beginning to perspire freely. At both bases and the axillae there had developed flatness below the level of the angle of the scapula with distant bronchial breathing and bronchophony. Above this zone were fine crepitant rales. Both Dr. E. A. Locke, who was called in consultation, and Dr. Morrison felt convinced that there was fluid in the chest, probably pus, but they were uncertain whether it was in one side or the other, or both.

On April 14, the fifteenth day of her illness, she was sent to the Boston City Hospital, with the provisional diagnosis of double empyema. An x-ray examination at that time showed increased density in the left lower lobe, suggesting consolidation rather than fluid. Dr. Lund then did paracentesis in both sides of the chest, in two places

in each side, with no result. For the next three days the patient's condition remained unimproved. On April 18, she began to cough up a great deal of foul pus, without relief, however.

On April 21st the left chest was again tapped. This time a few drops of thick pus were obtained through the needle inserted in the ninth interspace in the posterior axillary line. Resection was done of an inch of the ninth rib, with the evacuation of several ounces of thick foul pus, similar to that which the patient was expectorating, found as a thin layer between the lung and the chest wall. Drainage was established through a rubber tube inserted obliquely, with the skin sutured over the end to act as a valve.

On the following morning the patient's condition had not improved, and the right pleural cavity was explored a second time. A needle inserted through the tenth interspace near the spine, and directed upward, obtained a few drops of pus. The tenth rib was resected near the vertebra, and a few ounces of foul pus were found between the right lung and the spine. Drainage was established through a rubber tube.

The patient began to improve at once. There was profuse drainage through both tubes. The cough and expectoration subsided gradually. The sputum never showed any elastic tissue fibres. The temperature reached the normal level by the middle of May, 1915. The pulse rate remained elevated for another month. By the end of May, both wounds were granulating, and there was very little discharge through the small sinuses. On May 29th, an x-ray examination showed no evidences of fluid in the chest; there was some haziness throughout both lungs, but they were well expanded.

Through the summer, the patient improved steadily. She gained in strength and weight. Cough and expectoration ceased entirely. Both lungs became clear and expanded well; the chest became symmetrical.

### COMMENT.

This is a case of double empyema following pneumonia. As judged from the series of cases of empyema collected by Dr. F. T. Lord<sup>1</sup>, one case in fifty is bilateral.

On April 18, 1915, when this patient began to raise fetid pus in large quantity, there was a perforation of the lung tissue. The pus expectorated and the pus evacuated surgically were identical. Osler<sup>2</sup> speaks of perforation into the lung as one of the natural modes of cure of empyema. He quotes from an article by Traube, published in 1872, entitled, "On a Natural Mode of Cure in Purulent Pleuritic Exudate." There appear two ways in which an empyema may discharge through the lung: first, by opening into a bronchus and the formation of a fistula; and secondly, by a local necrosis of the pulmonary pleura, exposure of the parenchyma, and a soakage of pus through the spongy lung tissue into the bronchi. In the first way, pneumothorax usually, though not often, develops, and aggravates the danger. In the second way, pus is usually discharged without the formation of pneumothorax, and must be regarded as one of the most favorable modes of termination in empyema. We believe that in the case here re-

ported, the perforation of the lung was of the second type, but the drainage so established by nature was insufficient to bring about a cure without surgical assistance.

It is worthy of note that the pus in the left pleural cavity was a thin layer between the lung and the chest wall, and in the right, between the lung and the spine.

The x-ray plates in this case, although there was a definite localized empyema on either side, showed merely a general haziness of the lower part of the chest. The position and outline of the cavity were not shown distinctly on either side. Percussion, also, failed to localize the cavities. It is easy to see why this was the case on the right side of the chest, where the cavity lay in an unusual position,—between the mesial surface of the lung and the spine and vertebral portions of the ribs. The neighborhood of the spine, vertebral muscles, and rib angles in this position make it very difficult to detect a thin, flat cavity. The cavity on the left, though superficially situated, was not large, and was so localized that a needle pointed in the usual direction, upward and inward from the ninth interspace and posterior axillary line, failed to strike it. Aspiration higher up also failed the first time it was tried.

FIG. 1.—Showing position of pus cavities.

It is an interesting question, whether, when the history and physical signs strongly favor the presence of pus, but aspiration is negative, the chest should not be opened and a search under the guidance of the finger made. Granted that the needle is the right size and intelligently manipulated, aspiration may be negative. Being negative in this case, it was repeated on both sides in two places, although the chest was not opened until one week later. Repeated aspiration, however, may be dangerous. Alarming hemorrhage has followed such aspiration in the hands of one of the writers in two cases. In one

of these, the chest was opened and the pus found while the hemorrhage was going on, the tapping being negative as far as pus went. It is interesting that in this latter case, operation showed the pus in the same place as in the case reported, namely, between the inner surface of the lower lobe and the chest wall. The deeper the needle is pushed into the lung, the greater the danger of the serious hemorrhage which may result from wounding one of the large arteries near a bronchus. The oftener repeated the aspiration, the more danger of deep or careless work. It is so easy to miss a localized empyema or an abscess, that we believe when the physical signs and history are positive, one should open the chest and push about with one or two fingers. Pushing the lung from the chest wall cannot cause serious hemorrhage, and an empyema cavity always lies between the lung and the wall, except in the rare interlobar empyema which always in the writers' experience comes up near the surface of the lung.

A lesson from this case and the case mentioned which was complicated by hemorrhage, is never to be satisfied with a negative result till you have explored the space between the inner surface of the posterior lobe and the spine. The problems of localized empyema are more interesting and difficult than the so-called general empyema, which is found at the base of the lung behind, and in which there is no difficulty in finding the pus, as it lies just beneath the ribs at the point of election for tapping, namely, the ninth interspace in the posterior axillary line.

The x-ray has occasionally been of the greatest assistance, but, as stated above, was of no value in this case.

## A CASE OF BLOODY TEARS.

By M. J. KONIKOW, M.D., BOSTON.

THE extraordinary rarity with which bloody tears are seen in general practice may possibly justify the report of the following case:

A. M., 50, painter. Has been in good health, except for the last few months during which he had several attacks of slight nosebleeds. One of such nosebleeds started a couple of hours before I saw him. Ordinary means previously employed by him and members of his family had proven unsuccessful, and the physician's aid was sought.

Blood was freely flowing from the right nostril. An anterior tamponade failed to stop it, merely directing the flow backward. A complete stoppage of the flow was obtained only by a combined tamponade, anterior and posterior.

A few minutes after I succeeded in stopping the nosebleed, large bloody tears began to run down

the cheek from the right eye. Pressure, however upon the right nasal duct stopped this flow.

Of course, the source of these "tears" came from the blood that was caught between both tamponades and was forced into the nasal duct. So, physiologically, these "tears" were not tears at all, but the product of the backflow through the nasal duct.

True sanguineous lachrymation, *i.e.*, bloody tears produced directly by the lacrymal gland, is an extremely rare occurrence, and it is doubtful if it ever exists.

The *Index Medicus* mentions a few authors only who have reported cases of sanguineous lachrymation. F. R. Cross<sup>1</sup> reported a case of a girl of 21 who for several years had been suffering from bloody tears coming occasionally from the left eye. By excluding any other source, this writer thought the lacrymal gland responsible for this phenomenon. Hasner<sup>2, 3</sup> reported two cases of bloody tears, one in a girl of 13 who was exhibiting this phenomenon during the two years preceding her first menstruation; the other in a healthy young butcher where the cause of the trouble was located in a lentil-sized polyp of the upper conjunctiva. S. W. Ochapowski<sup>4</sup> reported a case of bloody tears, the cause of which he placed in the general hysterical character of the patient. With R. Spelleers<sup>5</sup> and R. Cross,<sup>6</sup> who reported similar cases of bloody tears, the literature on this subject is almost exhausted.

That bloody tears are not met with frequently, my own case fully confirms. In my twenty-three years as general practitioner this was the first case I came across.

### Society Report.

#### BOSTON SURGICAL SOCIETY (INCORPORATED).

##### TENTH MEETING.

A clinical meeting of the Society was held on Monday, February 7, 1916, at the Peter Bent Brigham Hospital, at 10 a. m.

Dr. Cushing demonstrated a series of interesting cases as follows:

1. Cerebellar tumor. (This case was operated upon later before the Society.) The patient showed loss of vision and choked disc. The fundus was demonstrated to the members of the Society by a new binocular ophthalmoscope.

2. Cerebellar tumor. Two weeks after operation; beginning to sit up for first time in six months.

3. Endothelioma, with Jacksonian epilepsy. A previous exploration in Chicago had failed to discover the tumor, which lay near to the vertex. Much subjective improvement after removal of the tumor.

4. Solid pituitary tumor with huge hernia of the brain, following decompression done at the Massachusetts General Hospital. Trans-sphenoidal operation done by Dr. Cushing disclosed an irremovable pituitary tumor.

5. Internal hydrocephalus. Decompression done in Chicago. Trans-sphenoidal operation by Dr. Cushing showed a dilated third ventricle with internal hydrocephalus.

6. Pituitary tumor with internal hydrocephalus. Similar to Case 5.

7. Ductless gland syndrome, probably pituitary. Male with feminine characteristics. Decompression with relief of long standing headache.

8. Headache of typical pituitary character. Coincident diabetes. Case under investigation.

9. Pituitary tumor. Female. Headache; blindness in one eye, and hemianopsia in the other. Under investigation.

10. Dislocation of the atlas. Traumatic. Six months' duration. There was some numbness of the hands. X-rays showed the lesion plainly. At operation reduction could not be accomplished, but the spinal canal was enlarged to relieve pressure. Marked improvement.

There was a lantern slide demonstration of specimens of brain tumors.

Following the demonstration Dr. Cushing operated on Case 1, cerebellar tumor; and Dr. John Homans operated on a case of gallstones and pancreatitis, with drainage of the gall-bladder and of an abscess in the region of the head of the pancreas.

The meeting then adjourned.

(Signed)

L. DAVIS,

Acting Secretary.

### Book Reviews.

*Progressive Medicine*. Edited by HOBART AMORY HARE, M.D., assisted by LEIGHTON F. APFLEMAN, M.D. Vol. xix, No. 3, September, 1916. Philadelphia and New York: Lea & Febiger, 1916.

This quarterly issue of a standard digest of advances, discoveries and improvements in medical and surgical sciences, contains reviews of diseases of the thorax, the skin, the nervous system, and obstetrics. The latter constitutes half the volume and is an elaborate summary of recent literature on the subject. The section on dermatology includes also recent experience with arseno-benzol and diarsenol in the treatment of syphilis, and is illustrated with a dozen excellent cuts. The section on the thorax includes diseases of the heart, lungs, blood vessels, blood and circulation. The volume is a valuable collection of important recent contributions to the literature on the subjects in question.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, OCTOBER 26, 1916

## EDITORS.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.  
An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## TWO IMPORTANT LEGAL DECISIONS.

In the weekly report of the United States Public Health Service for September 29, 1916, is recorded a recent important decision by the Michigan Supreme Court, relative to administration of the Workmen's Compensation Act. In the case of a workman injured by a sawmill accident, the employer refused to make compensation payments longer than nineteen weeks, on the ground that the employee's protracted disability was due to retardation of healing by preëxisting syphilis. The claimant denied that he had ever had this disease, and the Industrial Accident Board, adjudicating the matter, found that there was no suggestion of active disease in the applicant, prior to the injury. The diagnosis of syphilis was based on an unsworn laboratory report, whose validity was evidently called in question. The Board made no definite decision whether the period of the claimant's disability was or was not extended by the pres-

ence and action of the disease, but declined to relieve the respondent for the following reasons, as stated in the written opinion of its council.

"The legal question presented by the petition is an important one. If the correct rule for determining the length of time compensation for disability should be paid in case of an injury of this general character is found to be the one contended for by respondents, the result will be far-reaching. The question then to be determined in cases of continuing disability would be whether the injury should have healed, or whether it should have healed more quickly than it did, instead of the actual resulting disability. Instead of the plain question of fact as to the nature and duration of the disability which the injured man actually suffered, it would present for decision the question as to how much he should have suffered, and how soon he should have recovered, upon the theory that only a part of the disability was due to the injury, and the remaining part due to disease. In the opinion of the Board, the respondents' contention must fail. The compensation law does not fix any standard of physical health, nor does it make any exceptions for cases of injuries to men whose health is impaired or below the normal standard. Neither does it except from the benefits of the law the man who carries in his body a latent disease which, in case of injury, may retard or prevent recovery. The law by its expressed terms applies to every man who suffers disability from injury. It does not exclude the weak nor the less fortunate physically, but was intended for the workingmen of the State generally, taken as they are."

In awarding its opinion on this case, the Supreme Court commented in part as follows:

"We agree with the Industrial Accident Board that under the circumstances of this case the act does not contemplate any such apportionment of the period of disability as respondents ask for. Assuming that such disability is being prolonged by the disease, there is yet no point at which the consequences of the injury cease to operate. It is the theory of respondents, not that the consequences of the injury cease, but that they are prolonged and extended. There is no part of the period of disability that would have happened, or would have continued, except for the injury. The consequences of the injury extend through the entire period, and so long as the incapacity of the employee for work results from the injury, it comes within the statute, even when prolonged by preëxisting disease."

"The order of the Industrial Accident Board is affirmed."

On October 3 the Court of Appeals of Albany, N. Y., handed down a decision permitting the practice of healing by Christian Science without

a license, holding that, while the practice of healing by Christian Scientists would come within the legal definition of medical practice, the statute specifically exempts those who, in the treatment of bodily ills, pursue the tenets of any religion. This decision was awarded in the case of a Christian Scientist practitioner convicted in New York in 1912 and fined \$100 for practicing medicine illegally. This conviction was reversed by the Court of Appeals and a new trial ordered. The case was a test action instituted by the New York County Medical Society in 1911. In his opinion, reversing the previous decision, Justice Chase comments in part as follows:

"Practicing medicine, when unaccompanied by acts that are in themselves evil, vicious and criminal, is not a crime at common law, but only becomes illegal when a statute is violated. The Legislature, in enacting the law requiring medical practitioners to be licensed, wrote in an exception which applies to Christian Scientists, and which reads:

"This article shall not be construed to affect . . . the practice of religious tenets of any church. . ."

"It was conceded at the trial, according to the decision, that Christian Science is a religion based on the scriptures.

"The purpose of the general statute is to protect citizens and others of the state from being treated in their physical ailments and diseases by persons who have not had adequate or proper training, education or qualifications to treat them.

"The tenets of a church are the beliefs, doctrines and creeds of the church. The exception relates to the tenets of the church as an organized body as distinguished from an individual. It does not relate to, or except, persons practicing in accordance with individual belief.

"It appears from the record that it is a tenet of the Christian Science Church that prayer to God will result in complete cure of particular diseases in a prescribed individual case. Healing would seem to be not only the prominent work of the church and its members, but the one distinctive belief around which the church organization is founded and sustained.

"We think the exception in the statute in this state is broad enough to permit offering prayer for the healing of disease in accordance with the recognized tenets of the Christian Science Church. . .

"A person should not be allowed to assume to practice the tenets of the Christian Science or any church as a shield to cover a business undertaking. When a person claims to be practicing the religious tenets of any church, particularly where compensation is taken therefor, and

the practice is apart from a church edifice or the sanctity of the home of the applicant, the question whether such person is within the exception should be left to a jury as a question of fact."

This judicial opinion, written by Justice Chase, was concurred in by all of the five judges sitting with him, except Justice Collin, who dissented. Chief Justice Bartlett, in handing down the decision, added a memorandum in which he said, "I would go farther. I deny the power of the Legislature to make it a crime to treat disease by prayer." The judgment of the primary court was, therefore, reversed and a new trial ordered.

In commenting upon this decision, the Weekly Bulletin of the New York Health Department for October 7 refers to it as one "of grave concern to all who are interested. . . in protecting unsophisticated laymen from unqualified pretenders to the healing art."

"While the medical profession is engaged in increasing the requirements demanded of all who wish to begin the study of medicine, and in raising the standards of medical colleges and the exaction of qualifying examinations, in order to secure better service to the public, there are some among the laity who are unwilling to see the practice of the healing art advance beyond the standards of superstition, where the laying on of hands, the use of amulets, charms, signs and magic phrases are relied upon to destroy the parasites of infectious disease in the sick and to frighten them from the well. Are such as who refuse to recognize that a typhoid infection, a smallpox eruption, or even a broken leg is anything more than a state of mind, to be allowed to pass in this state as qualified under the law to attend the sick?

"May any scamp who wishes to turn healer for 'easy money,' claim immunity from the law by pretending that he has a divine mission to heal, that his practice is part of a religion, which he may easily invent to cloak his purpose?

"Instead of four years at high school, a year or two at a general college and a four-year medical course, followed by an exacting state examination, and perhaps by a year's service in a hospital, may one take thought over night and hang out his shingle in the morning as a Christian Scientist, or as anything said to be a religion?

"If this is to be so, and we are loath to believe it, it will be much harder upon the public, the lambs who will be exposed to the wolves, than upon the shepherd dogs (the qualified physicians) who endeavor faithfully to guard the flock!"

## PROGRESS OF POLIOMYELITIS.

DURING the past week the poliomyelitis epidemic has continued practically unabated in Massachusetts, though declining elsewhere throughout the United States and practically at an end in New York. On October 17 the number of cases in New York City reached a total of 9217 with 2373 deaths. In New York State outside of New York City, there had been, on October 1, 2388 cases. On the same date there had been 3877 cases in New Jersey, 1561 in Pennsylvania, 773 in Connecticut, 718 in Minnesota and 672 in Illinois. It is estimated by the United States Public Health Service that there have been 28,262 cases since July 1 in the United States.

In Massachusetts, on October 21, the number of cases during this month reached a total of 518, making 1533 since January 1. Since October 1, the disease has extended into twenty-two towns of this Commonwealth, where no cases had occurred during the preceding ten months. These newly infected towns are Andover, Athol, Belchertown, Deerfield, Easton, Egremont, Grafton, Halifax, Hatfield, Hollbrook, Hopkinton, Longfellow, Manchester, Mashpee, Northboro, Northbridge, Walpole, Wenham, Westwood, Whately, Wilbraham and Wilmington. The largest number of cases has been 380 in Boston, 14 in Holyoke and 51 in Quincy. There have been 38 cases in Malden.

The New York Health Commission has recently published interesting data of the epidemic in New York City, with the following comment on the social status of the patients and on details of the administrative control of the disease.

"It is interesting to record that up to September 30 a total of 16,267 cases of supposed poliomyelitis were reported to the Department of Health by physicians, nurses, and members of various households. Of these, up to September 30, 8630 were proved to be true cases.

"Attention is called to the close approximation of the case fatality in the Department of Health hospitals and the case fatality in the twenty-seven other hospitals which admitted cases during epidemic, the difference being only one hundredths of one per cent.

"From August 21 to October 18 there were discharged from the hospitals of the Department of Health 2053 cases. Of these, 66% showed evidences of paralysis of some degree; 18% showed that paralysis had wholly disappeared;

15% had not shown paralysis at any time in the course of the disease.

"Of 2715 cases, followed up carefully in the homes, it has been found that 1885 have a serious paralysis of one or both lower limbs and are unable to walk; 530 more were partly paralyzed in the lower limbs, although still able to walk; 273 had one or both arms totally paralyzed.

"Judging from the cases already visited by the agents of the relief societies operating under the control of the Committee on After-Care, it is found that between 75 and 80% of the cases with a persistent paralysis will fall in the class of people usually obtaining medical services free through dispensaries or hospitals."

During the past fortnight, further reports of discoveries regarding the disease have appeared in the daily press. Dr. Edward C. Rosenow, of the Mayo Foundation at Rochester, Minn., is reported to have expressed at a recent meeting of the New York Academy of Medicine his opinion that the tonsil is probably an important point of entry for the infection. Experiments in the pathological department of the Johns Hopkins Hospital in Baltimore, by Dr. Montrose T. Burrows, would seem to indicate that the disease may make its entrance by the intestinal tract through the medium of infected food. No final decision on any of these theories can, of course, be made without further official report and study. At the dinner of the Massachusetts General Hospital House Pupils' Alumni Association, referred to in a later editorial in this issue, Dr. Haven Emerson, health commissioner of New York, in his informal remarks, indicated his belief that none of the present theories advanced to account for the transmission of poliomyelitis would prove, or expresses, the entire truth. He narrated various significant epidemiologic facts observed during the current summer in New York with regard to the disease and expressed the belief that no single therapeutic method had proved of as great value as the simple withdrawal of cerebrospinal fluid by lumbar puncture. This diagnostic procedure has proved, not merely to relieve symptoms, but apparently definitely to mitigate the course of the disease. An extensive report based upon the experience of the entire epidemic will, of course, later be issued.

As leading article in the present issue of the JOURNAL we are glad to publish the text of the address recently delivered by Dr. Allan J. McLaughlin, Massachusetts Commissioner of Health, at a joint meeting of the Massachusetts

Homeopathic Medical Society and the Suffolk District of the Massachusetts Medical Society. Dr. McLaughlin expresses similar skepticism about all advanced theories of transmission of the disease. The attention of readers is particularly directed to his illuminating and comprehensive description of epidemic poliomyelitis and his analysis of the present epidemic in Massachusetts.

On October 19 the Massachusetts Association of Boards of Health held its quarterly meeting on Mt. Tom at Holyoke, Mass. The principal address was by Dr. Charles F. Bolduan, director of the Bureau of Public Education of the New York Health Department, on "What Has Been Learned from the New York Epidemic of Anterior Poliomyelitis." There were other addresses by Dr. Gardner T. Swarts of Providence, R. I., secretary of the Rhode Island State Board of Health, on "Quarantine Hysteria," and by Dr. J. F. Winchester of Lawrence, Mass., president of the American Veterinary Association, on "The Tuberculous Milch Cow."

In the issue of the JOURNAL for September 14 we noted editorially the first death of a physician from poliomyelitis during the present epidemic,—that of Dr. Earl C. Peck of Newton, Mass., on September 5. The second death of a physician from the disease was that of Dr. Arthur L. Hunt, health inspector of the District of Columbia, who died of poliomyelitis on October 8. His obituary notice is published in another column of this issue of the JOURNAL.

## THE STERILIZATION OF CRIMINALS.

A REPORT appearing in the September number of the *Journal of Criminal Law and Criminology* reminds us that the question of the right of the Commonwealth to deprive one of its citizens of the power to procreate is still unsettled, although the general legal opinion is that, in the case of the criminal at least, it has no such right. Recent years have seen a movement in favor of the more humane treatment of prisoners, a scientific approach to the study of criminology, but our knowledge of the etiology of crime is still in too nebulous a state to render wise legislative approval of sterilization of criminals in order that more criminals may not be bred.

If we are going to deprive of his power of procreation, say some, those who have been twice convicted of acts which constitute legal felonies—breaking an electric light bulb, obstructing a highway or cutting a strap in a harness (Iowa code)—we might just as well write above the doors of our penal institutions: *Lasciate ogni speranza, voi ch' entrate*.

The first sterilization law was passed in Indiana in the spring of 1907. Since that time twelve other states have passed such laws, but in two of them (Iowa and New Jersey) they have been found unconstitutional. In four other states bills have been passed and vetoed. In seven other states bills were introduced and defeated in the legislature. It would take entirely too much space to give the history of these measures in the various states. Suffice it to say that so much doubt has arisen as to the constitutionality of such a law as applied to criminals that it is nowhere enforced, with the exception noted above. A test case was brought in Iowa in 1914 (Davis vs. Barry *et al.*, No. 9-A Equity.) In his opinion, which was concurred in by the other judges then sitting, Judge MacPherson said: "(This) operation is to destroy the power of procreation. It is, of course, to follow the man through the rest of his life. The physical suffering may not be so great, but that is not the only test of cruel punishment; the humiliation, the degradation, the mental suffering, are always present and known by all the public, and will follow him wherever he may go. This belongs to the Dark Ages. . . And our conclusion is that the infliction of this penalty is in violation of the constitution, which provides that cruel and unusual punishment shall not be inflicted."

It is the opinion of those best informed in the matter that the question of sterilization was entered into rather too hurriedly, before in fact it was definitely known just what part heredity played in the propagation of criminals. An example of this tendency to rush in was furnished by the American Medico-Psychological Association, at its annual meeting in Baltimore in 1914, when it nearly gave the seal of its official approval to a resolution approving of marriage laws—indeed, would have done so had not an objection been registered by a few of the wiser heads.

At present the following states have laws dealing with the sterilization of undesirables: California, Connecticut, Indiana, Iowa, Kansas,

Michigan, Nebraska, Nevada, New Jersey, New York, North Dakota, Washington and Wisconsin. In Washington, Nevada,\* New Jersey, New York, Michigan and Kansas no operations have been performed. In Indiana, the first state to pass laws of this kind, no operations have been performed since 1908. Wisconsin has sterilized 24 feeble-minded, Connecticut 21 insane, and California 634 insane. The American Institute of Criminal Law and Criminology appointed a committee on the sterilization of criminals in 1914, which has made several reports on the subject. In their latest one† it reports that, as far as it has been able to ascertain, no attempt is being made to enforce any of the laws providing for the sterilization of criminals except in Washington, where the law is punitive. It further states that the law is carefully administered in the states where operations are being performed.

One aspect of the question which has not seemed to attract so much attention is that of the attitude of the sterilized criminal to society. Aside from the fact that he may cherish a deep-seated grudge against the powers that be, may he not be potent for evil in other ways? Let us assume that vasectomy is all that is claimed for it, that it will prevent procreation but will not interfere with sexual intercourse; will not the knowledge that he is immune from the possibility of having to assume the responsibility of paternity render him a dangerous influence in the community? Too often the fear motive is dominant in the lower-class girl, and does more to restrain her from sexual immorality than any ethical consideration. This fear, too, is not that of contracting disease—for she is often unacquainted with the method of transmission of venereal disease, and if she is informed is too ready to believe that her lover is not infected—but the fear of becoming pregnant. The discharged criminal thus finds the bars down and becomes an influence for the lowering of morals in his circle, and often a distributing center for disease.

#### THE MENTAL EXAMINATION OF CRIMINALS.

It is generally known among medical men that a large proportion of the floating popula-

tion of jails and workhouses are mentally defective. The vagabonds, prostitutes, the chronic alcoholics, the petty criminals of all kinds, if carefully put through mental examinations, would undoubtedly show many cases of aborted precoc, imbecility, constitutional inferiority and constitutional psychopathy. Some observers believe that as many as 60% of all petty criminals are abnormal mentally.

Although we are still a long way from recognizing a class of persons only partly responsible for their actions, the *demi-fous* as the French call them, we are beginning to deal with the problem of investigating the mentality of those convicted of crime. Dr. Healy's work at the Juvenile Psychopathic Institute in Chicago is well known, and there has recently been established at Sing Sing Prison a department of the Rockefeller Foundation to make psychiatric investigation of the population. Court and police officials in many cities are beginning to appeal to alienists in doubtful cases before taking punitive action. Finally, the literature is becoming filled with material dealing with the subject.

In the *Journal of Criminal Law and Criminology* for September, there are two papers bearing on this subject. Dr. Yerkes, who will be remembered at once in connection with the Yerkes-Bridges-Hardwick tests, makes a few remarks on the mental examination of police court cases. He believes that we are only just beginning to progress in this line, that each human being is a tremendously complex individual problem, and that no psychological norm has yet been established. He says that first of all, these cases must be superficially divided into several classes: 1, normal persons, the victims of circumstances; 2, psychopathic personalities; 3, mental defectives; 4, drug addicts; 5, physical wrecks. Other classes may also present themselves. Obviously, some of these classes are not suitable for psychological observation, Classes 1 and 5 especially. Members of Class 2 should be transferred to asylums and studied there. Yerkes urges that each case should be investigated entirely by a single person, who, besides making a complete mental examination, should go into heredity, the personal history and the social conditions which have formed the environment of the patient. He especially protests against the practice of appointing inadequately trained persons to positions as psychological examiners. "If our police system,

\* According to the best information available.

† Case pending before the courts, March, 1915.

‡ Sterilization of Criminals. Report of "Committee F" of the Institute. *Journal of Criminal Law and Criminology*, September, 1916.

courts, and penal institutions are to utilize the methods of psychology at all, it should be through the service of adequately trained professional psychologists.'

In the same periodical Dr. Guy G. Fernald writes on the mental examination of reformatory prisoners; his paper is largely constructive in character. In the Massachusetts Reformatory the inmates are not examined until they have been some time resident, in fact, the psychonological interview is timed for the latter end of the period of incarceration, when the early feelings of resentment or homesickness or rebellion or braggadocio, as the case may be, have passed. The method of applying uniform tests has been abandoned for several reasons: It was too time-consuming; some tests were not adaptable to all subjects; it did not reveal character defects and personality asymmetries; it was too inelastic and formal, and word of the tests was frequently passed around to such an extent that results were vitiated. The line of demarcation between the normal and subnormal, found by various observers among different criminological groups to fall somewhere between 25 and 89%, is in this Reformatory 58%. Of this subnormal group, Fernald says it is important to separate out those who are incapable of honest self-support without surveillance,—what he calls the "segregation group." These show readiness to falsify and striking egotism.

The constructive part of the examination is the last part, where the patient's intentions for the future are ascertained. He may be required, for example, to write out his own plan of living for the next five years, to make up for his past mistakes. His emotional reaction to this suggestion is illuminating. He is also asked why so many prisoners lead no better lives after release, why the reformatory is a good place to reform in, etc. Some prognosis can thus be formed as to his chances for making good when he leaves the reformatory.

These two writers both recognize the individuality of each problem, and emphasize that delinquents should be examined, not by any cut-and-dried methods, but by an intensive individual psychological study, and when this is grasped fully by criminologists we shall have a more enlightened manner of handling offenders. In too many instances, even where the custom of examining inmates mentally is in vogue, the method in use is the hasty and formal applica-

tion of some such scheme of tests as the Binet-Simon, often by an assistant or social worker, unskilled in psychology. Naturally the results obtained are of little practical use.

---

### THE MOSELEY MEMORIAL.

THE seventieth anniversary of Ether Day was observed at the Massachusetts General Hospital with appropriate ceremonies on October 16, 1916. In the morning there were clinics and demonstrations at the Hospital and in the afternoon the award of diplomas to house officers and the Ether Day address by Dr. Haven Emerson, health commissioner of New York. It is expected that this address will be published in full in a later issue of the JOURNAL.

The anniversary of Ether Day has particular interest this year on account of the formal dedication and opening of the Moseley Memorial Building, the new administrative headquarters of the Hospital. This building, representing a cost of about \$250,000, is the gift of Mr. Charles W. Moseley, of Newburyport, Mass., in memory of his cousin, Dr. William O. Moseley, a former house pupil at the Massachusetts General Hospital, who met his death in 1879 while climbing the Matterhorn. At the dinner of the House Pupils' Alumni Association, held in the evening at Hotel Vendôme, a narrative of Dr. Moseley's life was given by Dr. John W. Eliot, his classmate. Dr. Haven Emerson spoke on the work of the New York Health Department during the recent epidemic of poliomyelitis and there were other addresses by Dr. Elbridge G. Cutler, the retiring president; by Dr. Hugh Cabot; and by Dr. William F. Whitney, the newly elected president of the Association for the ensuing year.

---

### SUFFOLK DISTRICT CENSORS' EXAMINATION.

ATTENTION is called to the notice of examination for admission to the Suffolk District of the Massachusetts Medical Society, which was published in last week's issue of the JOURNAL, and is repeated in the present. The importance from every standpoint of belonging to the official medical organization of the state in which he

lives should be obvious, not only to every practitioner, but to every recent graduate in medicine. As an immediate sequel to state licensure, membership in the state medical Society is the ultimate index of approved competence. All qualified regular physicians, who have not already done so, should take the coming examination with a view to permanent membership in the Massachusetts Medical Society.

### MEDICAL NOTES.

**LONDON DEATH RATES IN AUGUST.**—Statistics recently published show that the total death rate of London during the month of August, 1916, was only 10.6 per thousand inhabitants living. Among the several districts and boroughs the highest rate was 14.5, in Holborn, a crowded central slum, and the lowest was 7, in Hampstead, an open suburb on the north.

**ALVARENGA PRIZE.**—The College of Physicians of Philadelphia announces that the next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about \$250, will be made on July 14, 1917, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College on or before May 1, 1917.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper, and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The Alvarenga prize for 1916 was not awarded.

**PREVALENCE OF DISEASE IN THE UNITED STATES.**—The weekly report of the United States Public Health Service for October 6 states that during the month of August, 1916, there were reported in Arkansas 1117 cases of malaria and 206 of typhoid. In California during the same period there were 161 cases of malaria, 57 of pellagra, and 163 of typhoid.

**TWO MEETINGS OF MEDICAL INTEREST.**—The twenty-sixth annual session of the New York and New England Association of Railway Surgeons was held in New York City on Wednesday and Thursday of last week, October 18 and 19, under the presidency of Dr. D. H. Lake of Kingston, Penn. There were clinics at the New York City Hospitals. The address in surgery was on "Some Practical Points of the Cancer Problem," by Dr. William S. Bainbridge; and among other papers presented there were symposia on "Anesthesia" and "Bone Surgery." Dr. Fred B. Lund of Boston presented a paper on "The Value of Local Anesthesia in Surgery."

The thirteenth session of the Massachusetts State Conference of Charities is to be held in Lowell, Mass., on October 25, 26 and 27. The principal topics to be considered at the several sessions are "Next Steps in Child Welfare," "Present Needs of Working Children," "Housing and Social Progress," "Organized Charity and Social Progress," and "Aid to Mothers with Dependent Children."

On October 25, a meeting of the Boston Conference on Illegitimacy was held at Tewksbury, Mass., at 3.30 p.m. A cordial invitation to attend this meeting is extended to interested members and guests of the State Conference of Charities, to whom an opportunity was afforded to observe the various activities of the infirmary at Tewksbury.

**POSSIBILITY OF NOVOCAINE ADDICTION.**—In the issue of the JOURNAL for October 5, we commented editorially on the possibility of the establishment of novocaine addiction among those for whom the obtainment of cocaine has become impossible. In this connection our attention has been called to the following passage from the "London Letter" in the *Journal of the American Medical Association* for August 26, 1916, on the subject of substitutes for cocaine in dentistry.

"The accidents arising from the use of cocaine by the large number of unqualified persons who practice dentistry has led the Government to restrict the use of this drug. The Government has arranged to make available a sufficient supply of novocaine for use as a local anesthetic, in place of cocaine, by practicing dentists, whether registered or unregistered. As the supply is not immediately available in the particular forms usually required for dental purposes, and three or four weeks may elapse before it can be made available in these forms, the Government has granted a temporary permit to all persons engaged, July 28, 1916, in the bona fide practice of dentistry, but not to purchase preparations containing more than 1% of cocaine, adapted for use as local anesthetic in connection with dental work, subject to the condition that the preparations are used as local anesthetics in connection with such work and for no other

purpose. The permit will remain in force until September 15 next. After that date it will not be legal for unregistered dentists to continue to use cocaine preparations. Public notice will be given in good time, stating how and where the novocain preparations can be obtained. The Government calls attention to the fact that eucain is being manufactured on an increasing scale in this country, and it is probable that considerable supplies of this drug also will be available shortly to meet the demand for local anesthetics for dental purposes."

As a matter of fact, we are informed that since the Harrison law went into effect, there have been instances in which cocaine habitués tried to make use of novocaine, but to their vexation found it to have no stimulating or exhilarating properties.

**CHOLERA IN JAPAN.**—During the past summer Asiatic cholera has been epidemic in Japan, where a total of about 3000 cases have occurred. Report from Tokyo, on September 12, stated that the disease had recently made its appearance in that city, where there had been about eighty cases with thirty deaths. The weekly report of the United States Public Health Service for September 29, 1916, noted the occurrence of 353 cases of Asiatic cholera at Osaka, and of 262 cases, with 107 deaths, in Nagasaki.

#### EUROPEAN WAR NOTES.

**AMERICAN RED CROSS IN SERBIA.**—An insight into gratifying civilian relief activities, which are being directed in Serbia for the American Red Cross by Mr. Edward Stuart and Dr. Edward Ryan, is given by two letters just received at Red Cross headquarters from Mr. Stuart in Belgrade, the captured former Serbian capital, dated August 28 and September 13. Mr. Stuart first went to Europe for the American Red Cross early in 1915 as the head of a supplemental force of skilled American sanitarians and participated in the suppression of the deadly typhus epidemic of that year, while Dr. Ryan piloted into Serbia by way of Greece, some months prior to that, the first detachment of American Red Cross surgeons and nurses which served in Belgrade, caring for both Serbian and Austrian wounded and typhus victims for over a year.

An Associated Press dispatch, as late as October 9, said, owing to the inability of the American Red Cross relief commission to obtain further supplies from Roumania, the work directed by Mr. Stuart probably would be terminated with the exhaustion of the supplies on hand toward the end of November. The number of persons depending on the commission for relief of one kind or another was then given at 36,000. Approximately 3180 tons of food, in addition to 10 earloads of clothing, had been distributed.

The American Red Cross by means of relief materials obtained in the United States and Roumania and contributed by the Swiss Government, and aided by Austrian military authorities, had succeeded in tiding the needy Serbians over the lean period of the year while the crops were growing. While starvation conditions had been relieved, there was still an urgent need for clothing, and Mr. Stuart hoped this want would be supplied from the United States.

The first of the two letters from Mr. Stuart, above referred to, was written just after Roumania had declared war upon Austria-Hungary. Roumania has been the source of large stores of relief supplies which Mr. Stuart has been purchasing for the American Red Cross not only for the relief work he is directing in Belgrade, but for Dr. Ryan's party to the south. Prior to the declaration of war, Mr. Stuart had procured across the Roumanian frontier 257.5 earloads of supplies, including eighty earloads of maize shipped from Bechet.

**WAR RELIEF FUNDS.**—On Oct. 21 the totals of the principal New England relief funds for the European War reached the following amounts:

Secours National Fund .....	\$220,154.92
Belgian Fund .....	161,327.02
French Wounded Fund .....	127,627.07
Armenian Fund .....	71,844.46
French Orphanage Fund .....	66,984.91
Surgical Dressings Fund .....	48,810.25
Polish Fund .....	45,885.83
Italian Fund .....	26,028.04
Prince of Wales Fund .....	15,469.67
Permanent Blind Fund .....	13,379.12
French Phthisis Fund .....	5,277.00
Russian Refugees Fund .....	2,609.00

#### MEXICAN NOTES.

**MEDICAL PREPAREDNESS.**—In a recent issue of the *Military Surgeon* is published an editorial commenting on the present preparedness of the United States Army Medical Corps as contrasted with its inefficiency at the time of the Spanish-American War, and referring also, in conclusion, to the demonstrated efficiency of the Medical Reserve Corps:

"1898 found the medical department of the Army unprepared; 1916 finds it in a high state of efficiency. The lesson of the Spanish-American War was a bitter one. The Medical Corps has 'chewed over it' ever since and determined that the mistakes (many of them due to ignorance and deficient equipment and personnel) would never be repeated. It has been the 'under dog' whenever promotion, increase of numbers and appropriations by Congress have been concerned. It has maintained an uphill fight with the line, as well as with the public, but it has come into its own.

"Whatever sharp criticisms have been made with regard to the unpreparedness of State and Federal government in connection with the present mobilization, the doctors have not been caught napping. Few in numbers—for the ample provisions of the Army bill had not been established by law—the corps had foreseen the emergency and provided for it. Our troops at the border are actually safer than they would be at home, surrounded by every protection known to modern science, due to the developments in camp sanitation and preventive medicine since 1898. The earnest, but untrained medical officers of the guard have received at least theoretical instruction during these years, and in camp and garrison they have at their elbows the cream of the Medical Corps as their advisers.

"Hasty and superficial as were necessarily the physical examinations at the armories from which raw recruits were unwisely (as we knew at the time) rushed to the border, they were as far as possible checked up by responsible U. S. A. officers, not influenced by the 'fear or favor' which must naturally hamper those in the guard, especially in passing on their own commanding officers.

"Had the original plan of mobilizing in home camps been adhered to, the result would have been far better, but even with chaotic conditions and feverish haste of the first few days, good work was done in weeding out the unfit, though willing, candidates.

"Complaints about bad food, neglect, suffering on trains, poor hospital accommodations, etc., were bound to come, and much sympathy has been expended on our citizen soldiers, which they generally decry. Of course, the medical department is the scapegoat. The doctors are not to blame. As in 1898, it is the company commanders who are more often at fault, through lack of experience rather than neglect in their part.

"In the regular army the line and Medical Corps work together for a common end—to maintain the efficiency of the organization. Lead Captain Andrews' 'Fundamentals' and the explanation will be clear, even to the layman.

"Every captain is responsible for the health, physical and moral, of his men and cannot shift that responsibility. Before his own ease, comfort, or convenience, these should be paramount. In the army, on the train or transport, in camp, and on the field of battle, they look to him. The doctor is equally interested in maintaining their efficiency and will cooperate, as far as possible, not only in strictly medical matters, but in matters not entirely within his own sphere. The company commander will heed his advice, or treat it lightly. This was the great lesson of 1898 and should be that of 1916. Incidentally, attention may be called to the fact that the Medical Reserve Corps (inactive) has also made good. Many of its members have been ordered to the border, to home and foreign stations, and

have responded promptly and cheerfully like true soldiers. There has been nothing spectacular about their departure. One by one, as their orders came, they have donned the khaki, dropped their work and devoted themselves with single purpose and energy to such duty as was assigned to them, regardless of loss of patients or financial considerations.

#### BOSTON AND NEW ENGLAND.

**THE WEEK'S DEATH RATE IN BOSTON.**—During the week ending Oct. 21, 1916, the number of deaths reported was 213, against 179 for the same period last year, with a rate of 15.68, against 12.44 last year. There were 34 deaths under one year of age, against 28 last year; and 65 deaths over 60 years of age, against 54 last year.

The number of cases of principal reportable diseases were: diphtheria, 31; scarlet fever, 14; measles, 3; whooping cough, 11; typhoid fever, 3; tuberculosis, 34.

Included in the above were the following cases of non-residents: diphtheria, 10; scarlet fever, 5; typhoid fever, 4.

Total deaths from these diseases were: diphtheria, 2; measles, 2; typhoid fever, 3; tuberculosis, 16.

Included in the above were the following deaths of non-residents: measles, 2; tuberculosis, 1; typhoid fever, 3.

**BROCKTON (MASS.) HOSPITAL.**—The annual report of the Brockton Hospital, Dr. Loring B. Packard, superintendent, states that the total number of ward patients treated during the past year was 1162, an increase of 8% over the previous year. There was an increase in the out-patient department of 17.5%. The maternity service, however, has shown the greatest gain. The capacity of the Hospital is not sufficient to care for its rapidly growing demands, and plans are being made to raise funds sufficient to erect additional buildings for nurses' home and wards.

**BRIGHAM HOSPITAL TRAINING SCHOOL.**—The graduating exercises of the school for nursing at the Peter Bent Brigham Hospital, Boston, were held on Thursday evening of last week, October 19. There was a reception following the award of diplomas to 22 nurses.

**NEW ENGLAND TUBERCULOSIS CONFERENCE.**—The third annual New England Conference on Tuberculosis was held in New Haven, Conn., on October 12, 13 and 14, with three hundred delegates in attendance. The principal topics of discussion were compulsory health insurance and the various methods of combating tuberculosis. Leading addresses were made by Mr. Bailey B. Burritt and Edward Hochhauser of New York, and Dr. Joseph J. Pratt and Mr. Seymour H. Stone of Boston.

**VERMONT MEDICAL SOCIETY.**—The 103d annual meeting of the Vermont Medical Society was held at St. Johnsbury, Vt., on October 12 and 13. The leading address was by Dr. John R. Williams, of Rochester, N. Y. Dr. Clarence H. Beecher of Burlington, Vt., was elected president of the society for the ensuing year.

**HOSPITAL BEQUEST.**—The will of the late Sarah C. Winn of Cambridge, Mass., which was recently filed at the Middlesex Probate Court, contains a bequest of \$1000 to the Nantucket Cottage Hospital.

**COURSES FOR DENTAL NURSES.**—The Forsyth Dental Infirmary has established a course for dental nurses, planned to conform with the dental registration law passed in Massachusetts last year. By this law dental nurses or hygienists are permitted to work in any public institution, but not in private offices. Candidates for entrance to this course must be 18 years of age, and must present certificates of graduation from approved high schools or the equivalent of a four-year high school course. A small tuition fee is charged.

### Massachusetts Medical Society.

#### ESSEX NORTH DISTRICT MEDICAL SOCIETY.

A quarterly meeting of Essex North District Medical Society was held at Wolfe Tavern, Newburyport, October 11, 1916, with the President, Dr. F. B. Pierce of Haverhill in the chair.

An interesting and classical paper was presented by Dr. Henry Jackson, of Boston, upon "Abdominal Pain." A valuable discussion upon the paper occurred, opened by Dr. C. E. Durant of Haverhill.

Following the scientific section of the program, the question of the injustice of the Workmen's Compensation Act of Massachusetts, toward employee and physician, was considered, and methods for alleviation were discussed.

It was voted that the business of the First Legislative Convention of Massachusetts Physicians, on Sept. 20, 1916, be ratified.

It was voted that the fund raised by the dollar assessment upon members of Essex North, called on Aug. 16, 1916, be devoted to the work of its Committee upon the Workmen's Compensation Act, as specified in its call.

The next meeting of the Society will be held Wednesday, January 3, 1917, at Haverhill, and the reader will be Dr. J. L. Morse, of Boston.

J. FORREST BURNHAM,  
Secretary.

### Miscellany.

#### RÉSUMÉ OF COMMUNICABLE DISEASES FOR SEPTEMBER, 1916.

**INFANTILE PARALYSIS** has practically monopolized the attention of the Department during the month of September. The other important facts on the communicable disease reports for the month were the small number of cases of diphtheria and the explosive outbreak of typhoid fever in Lynn.

**PREVALENCE.** The number of cases of communicable diseases reported to this Department was somewhat in excess of the figures for September, 1915. This was due largely to the increased prevalence of anterior poliomyelitis. The other common communicable diseases, with the exception of diphtheria, have maintained their usual prevalence in the State.

	TOTAL CASES REPORTED		
	SEPT., 1915	SEPT., 1916	AUG., 1916
Cases .....	2959	3234	3142
Case incidence per 100,000 population	80.2	85.5	83.2

**Measles.** There has been a still further decline in the number of measles cases reported to this Department. There are no cities or towns in the Commonwealth at the present time which are having an unusual amount of this disease.

	TOTAL CASES REPORTED		
	SEPT., 1915	SEPT., 1916	AUG., 1916
Cases .....	156	175	595
Case incidence per 100,000 population	4.2	4.6	15.7

The following cities and towns have exceeded their measles endemic index for September:

(Endemic index signifies the average for five years of reported cases exclusive of epidemics. This index is applied to each city and town for each month for every communicable disease. The numbers in parenthesis after the names of each city and town indicate the endemic index for that city or town. The numbers without parenthesis indicate the cases reported during the current month.)

Fall River .....	(6)	15
Lowell .....	(5)	29
Southampton .....	(0)	7

**Diphtheria.** The reduction in the number of reported cases of this disease during September as compared with the same month of last year is striking. On account of the fear of infantile paralysis, many of the schools of the Commonwealth are to remain closed. It will be interesting to note whether this has had any real influence upon the number of cases.

	TOTAL CASES REPORTED		
	SEPT., 1915	SEPT., 1916	AUG., 1916
Cases .....	697	470	460
Case incidence per 100,000 population	18.9	12.4	12.2

While there have been no marked outbreaks of this infection, a number of towns have exceeded their endemic index for the month of September:

Cambridge .....	(14)	29
Natick .....	(0)	14
Fitchburg .....	(3)	23
Ludlow .....	(0)	13
Westfield .....	(1)	10

**Whooping Cough.** There have been no striking features about the whooping cough situation during the month of September. The number of cases has increased slightly over those reported last month and has remained about the same as September of last year.

TOTAL CASES REPORTED			
Cases .....	SEPT., 1915	SEPT., 1916	AUG., 1916
.....	465	271	387
Case incidence per 100,000 population	12.6	7.2	10.2

The following cities and towns have exceeded their whooping cough endemic index for the month of September:

Fall River .....	(6)	29
Brookton .....	(1)	17
Cambridge .....	(9)	16
Haverhill .....	(1)	13

**Typhoid Fever.** There has been an increase in the number of cases of typhoid fever reported to this Department, both as compared with August of this year and September, 1915. This increase has been due largely to the explosive, milk-borne outbreak in Lynn, which will be described under the head of epidemics. However, Fall River has shown an unusual prevalence of typhoid fever and North Adams has reported considerably more than the average number of cases.

TOTAL CASES REPORTED			
Cases .....	SEPT., 1915	SEPT., 1916	AUG., 1916
.....	322	373	265
Case incidence per 100,000 population	8.7	9.8	7

The following cities and towns have exceeded their typhoid fever endemic index for the month:

Fall River .....	(18)	53
Lynn .....	(49)	88
North Adams .....	(43)	9

**Scarlet Fever.** The number of scarlet fever cases reported to this Department shows an increase when compared with last month, and a decrease when compared with the same month of last year. There have been no marked features of the scarlet fever situation.

TOTAL CASES REPORTED			
Cases .....	SEPT., 1915	SEPT., 1916	AUG., 1916
.....	299	203	178
Case incidence per 100,000 population	8.1	5.4	1.7

The following cities and towns have exceeded their scarlet fever endemic index for September:

Marion .....	(0)	5
Norwood .....	(0)	6

**Pulmonary Tuberculosis.** There are no interesting facts to report about pulmonary tuberculosis for the month. There were practically the same number of cases reported during the month just closed as the same month of last year.

TOTAL CASES REPORTED			
Cases .....	SEPT., 1915	SEPT., 1916	AUG., 1916
.....	610	602	589
Case incidence per 100,000 population	16.5	15.9	16.6

**Rare Diseases.** Dysentery was reported from Boston (22), Lexington (1), and Haverhill (3). Dog-bite was reported from Attleboro (1), Brockton (1), Fall River (1), Hull (3), and Lowell (1).

Cerebrospinal Meningitis reported from Boston (7), Lowell (3), Fall River (1), North Adams (1), Greenfield (1), Worcester (1), Everett (1), and Haverhill (1).

Pellagra was reported from Boston (1), Lynn (1) and Worcester (3).

Trachoma was reported from Boston (9), Chelsea (2), Hanson (1), and Lowell (1).

Malaria was reported from Boston (6), Newton (1), North Attleboro (2), Worcester (1), Fall River (1), Everett (1), Dedham (1), Haverhill (1), Cambridge (1), Uxbridge (3) and Chelsea (1).

Tetanus was reported from Nantucket (1) and Worcester (1).

Septic sore throat was reported from Boston (4), Amherst (1) and Taunton (1).

#### EPIDEMICS.

**Anterior Poliomyelitis.** Anterior poliomyelitis has continued to be reported from all parts of the State during the month of September. The total number of cases for the month was 626. This makes a total of 1016 cases reported to this Department since the first of January. For the sake of clearness, the special features of the disease will be discussed under individual heads:

**Distribution.** The distribution of the cases constitutes one of the peculiar features of the epidemic. This applies to the State as a whole, as was stated last month. There is a distinct localization of foci of infection.

**Report of Cases.** The reports from Adams and North Adams indicate that in this vicinity the infection has exhausted its susceptible period. In Pittsfield there has been a gradual increase in the number of cases reported during the month, with an additional focus of infection in the neighboring town of Dalton. There were no cases reported from the Greenfield-Montague area during September. This is also true of the lower border of the State in the Dudley-Webster

area, while Worcester reported only seven cases during the month.

The focus of infection, localized along the Merrimac River, mentioned in last month's summary, has continued to be an important factor of the month's report. There has been some extension of the infection to North Andover, Boxford, Georgetown, Newbury and Southboro. However, at the present time, the two most important foci are Boston and the Connecticut Valley area, with Holyoke as a center. Holyoke has continued to report cases in increasing numbers. This can also be said of Springfield, while Westfield and Northampton have remained quiescent.

The Metropolitan area has become a very active focus of the infection. Boston, which only reported eight cases in July and August, had 172 in September. Many of the surrounding towns have begun to report cases in small numbers, and it appears that the area will become the most important focus of the infection within the State.

*Characteristics.* Up to the present time the cases of anterior poliomyelitis have continued to affect the usual age group. The majority of the cases are under ten years of age. This characteristic is one of the most constant features of the disease. Any theory that will explain this infection must satisfactorily explain the constancy with which this age group of the population is attacked.

The following is a list of the cases reported from the various cities and towns during the month of September:

Boston	172	Weymouth	3
Holyoke	59	East Bridgewater	3
Springfield	39	Leominster	3
Pittsfield	32	Milford	3
Malden	18	North Attleboro	2
Cambridge	14	Tisbury	2
Newburyport	13	Boxford	2
Quincy	12	Danvers	2
Somerville	10	Hamilton	2
Everett	10	Saugus	2
Lynn	9	West Newbury	2
Chicopee	8	Newbury	2
Amesbury	9	Ludlow	2
Beverly	8	Monson	2
Medford	9	Hillieria	2
Revere	8	Melrose	2
Worcester	7	Waltham	2
North Adams	8	Woburn	2
Adams	5	Brookton	2
Dalton	5	Winthrop	2
Haverhill	5	Blackstone	2
Newton	5	Fitchburg	2
Lowell	5	Barnstable	1
South Hadley	5	Bourne	1
Braintree	5	Great Barrington	1
Dedham	5	Mount Washington	1
Chelsea	5	Otis	1
Andover	5	Stockbridge	1
Warren	5	Mausfield	1
West Springfield	4	Taunton	1

*Mortality.* From the incomplete records received by this Department, the anterior poliomyelitis fatality rate for September was higher than for August. There were 626 cases reported with 136 deaths, giving for a fatality rate 21.6, as compared with the fatality rate of 15.2 for August. A more detailed analysis of these rates will be made when the final and complete figures are received from the Secretary of State's office.

*Typhoid Fever.* Beginning August 28, until the end of September, there were reported from Lynn 114 cases of typhoid fever. This outbreak illustrates very strikingly the extensive character of milk-borne typhoid fever, for the investigation of this epidemic showed that all of the cases were on the road of a single milk dealer.

A careful analysis of the source of this milk dealer's supply was made. Most of the milk was produced upon his own farm. Smaller quantities were purchased regularly from an adjoining farm, while for a short period a temporary supply was secured through a neighboring contractor, to whom it came from New Hampshire. These sources of supply have all been thoroughly investigated and examination of the individuals having to do with the handling of milk secured. While the primary source of the infection of this milk supply has not been definitely proven, the reculturing of the specific individuals is not yet complete.

This milk supply was excluded from the city of Lynn until the dealer installed a modern pasteurizing plant.

A detailed report of this outbreak will be published in the later number of the *Bulletin*.

## ARMY SURGEONS AS MILITARY COMMANDERS.

In the issue of the *Paris Médical* of April 1, 1916, quoted in the *British Medical Journal* of September 30, Dr. H. Raymondaut narrates the story of two French surgeons who

rose to high military command during the Napoleonic Wars.

"Jean Pierre Joseph Bruyère was born in 1772 and served in the campaign of Italy as a surgeon of the first class. Preferring arms to the doctor's gown, he obtained, through the influence of Larrey, a captain's commission. He was a first-class fighting man and promotion was rapid. As colonel of the 23d Chasseurs he went through the campaigns of 1805 and 1806, being made brigadier-general after the battle of Jena. He was created a baron of the Empire in 1808 and a count in 1811. As a general of division he commanded Masséna's light cavalry in the Russian campaign in 1812. He was a man of impetuous valour, and was wounded at Eylau, Wagram, and Moscow, finally dying after amputation through both thighs at the battle of Bautzen in 1813. The other, Jean Baptiste Rusea, was born in 1759, and served as a medical officer in the army of Italy in 1793. In that campaign he was given a combatant commission, and for its conduct at Loasso he was made a brigadier-general on the field of battle. He was promoted general of division in 1799. He was severely wounded at Lodi, and again at Trebbia. In 1801 he was in command of the island of Elba, in 1814 he was killed on the ramparts of Soissons, being then at the head of a division of the National Guards."

Paul Triare, in his "Dominique Larrey and the campaigns of the Revolution and the Empire," also quoted in the same issue of the *British Medical Journal*, recounts the adventures of Colonel Lawless of the Scottish Legion:

"a learned physician who had been professor of physiology in the University of Dublin. His taste for soldiering and his hatred of England led him to take service as a combatant under Napoleon. He was wounded at Kulm in 1813, and Larrey amputated his leg below the knee. Lawless, who as a doctor knew the dangers of the hospitals of that time, mounted his horse immediately after the operation and rode straight to Mayence, here the first dressing was taken off. Thence he made his way to France, arriving there in good condition without any fresh dressing. Marbot in his *Mémoires* mentions Captain Fournier, adjutant-major to General Morland, commander of the *chasseurs à cheval* of the Imperial Guard. He had entered the army as a surgeon, but through Morland's influence obtained a combatant commission, and was killed with his chief at Austerlitz."

In our own country, the career of General Leonard Wood may be pointed out as a distinguished example of an army surgeon attaining high military command.

#### APPOINTMENTS.

BOSTON DISPENSARY.—Dr. Maynard Ladd has just been appointed Physician-in-chief of the Children's Department of the Hospital for Children of the Boston Dispensary, succeeding Dr. Arthur A. Howard. This appointment is made by the Dispensary, on the nomination of the Harvard Medical School. Dr. Ladd is instructor in pediatrics in the Harvard Medical School, is consultant physician of the Children's Hospital, the Floating Hospital and of the Boston Nursery for Blind Babies; a member of the American Medical Association, the American Pediatric Association, the Massachusetts Medical Society, etc. The Boston Dispensary Hospital for Children, the children's out-patient clinics, and the children's preventive clinic will be under his charge. Teaching in pediatrics to students of the Harvard Medical School will be carried on at the Dispensary under his direction. Dr. Elmer W. Barron will continue as Associate Physician of the Department, and will give instruction, as in the past years, to students of the Tufts Medical School.

#### RECENT DEATHS.

DR. DAVID FRANCIS LINCOLN, a retired Boston physician, hygienist and author, died suddenly, October 17, at his home, 131 Myrtle street. Dr. Lincoln was born in Boston, January 1, 1841, and was the son of William L. Lincoln. He studied at Harvard, was graduated in the class of '61 (the same class as Drs. H. P. Bowditch and O. W. Holmes), and three years later from the Harvard Medical School. For eighteen months during the Civil War, he was acting assistant surgeon in the United States navy, and thereafter for a long time he devoted his attention to nervous diseases and did more or less lecturing and writing in connection with Hobart College at Geneva, N. Y., after having retired from actual practice. At one time he was secretary of the American Social Science Association and he was a member of the Twentieth Century Club. He was the author of a number of medical works, published from time to time, and was a frequent contributor to medical journals. He never married. His survivors are three brothers, Walter M. Lincoln of the Brookline Savings Bank, William E. Lincoln of the Boston real estate firm of William Lincoln & Son, and Rev. James Otis Lincoln of San Francisco, Cal.

Dr. Lincoln was a Fellow of the Massachusetts Medical Society from 1865 until 1883, when he resigned. He moved to Geneva, N. Y., in 1881.

DR. VINCENT VON CERNY, senior professor of surgery at the University of Heidelberg, has died recently at the age of seventy-four years.

DR. ALBERT FRANKEL, who died in Berlin on July 6, was born in 1818. He was one of the earliest pupils of von Leyden, and was a nephew of the famous Traube. For many years he was director of the medical section of the Urban Hospital in Berlin, where he was a prominent physician and enjoyed an extensive consultant practice. His chief distinction is due to his discovery of the pneumococcus as the etiologic agent of lobar pneumonia; but in spite of this and of his notable contributions to medical literature on the subject of respiratory diseases, he never received a university appointment. He was a founder and for many years president of the Association for Internal Medicine of Berlin.

DR. HERBERT MARSHALL HOWE, who died on October 1 at Bristol, R. I., was born in Roxbury, Mass., on July 16, 1841. He received the degree of M.D. from the Medical College of the University of Pennsylvania in 1865, and thereafter served for five years as resident physician of the Episcopal Hospital, Philadelphia. He then relinquished the practice of medicine and went into business, in which he made a large fortune. He is survived by his widow, four daughters, and five brothers.

DR. ADONIRAM BROWN JUDSON, who died on September 20 in New York City, was born in 1837. He received the degree of A.B. from Brown University and that of M.D. from Harvard. He made a specialty of orthopedic surgery and was president of the American Orthopedic Association in 1891.

DR. EDWARD KIRSCHNER, who died recently at Hagerstown, Md., was born in 1839. He was assistant surgeon aboard the battleship *Cumberland* when it was sunk by the *Merrimac* during the Civil War. Subsequently he became a United States Medical Inspector, retiring with the rank of Commander.

DR. JOSEPH L. LOCKARY, of Roxbury, Mass., who died recently at St. Stephens, N. B., was a native of the latter city. He studied medicine at McGill University and at the Harvard Medical School, from which he graduated in 1897. He was a Fellow of the Massachusetts Medical Society. He is survived by one son.

DR. WILBUR P. MARBLE, of New York City, who died on August 30, at Kennebunkport, Me., was born in 1863. He was a practitioner of ophthalmology in New York. He is survived by his widow and one son.

DR. GEORGE WHITEHOUSE RYAN, who died at Boston on September 16, was born in this city on July 16, 1871. After attending the United States Naval Academy, he received the degree of M.D. from the Tufts Medical School. After serving as an ensign during the war between Spain and the United States, he resumed the practice of medicine, and for several years served as surgeon-in-chief at the Brockton, (Mass.) Relief Hospital and at the Grace Hospital, Boston.

DR. EZRA BRADWAY SHARP, who died on August 23, at Camden, N. J., was born in 1861. He received the degree of M.D. from the University of Maryland in 1888, and since 1897 had practiced his profession in Stomach, where he was instructor in diseases of the stomach at the local polyclinic hospital.

DR. EUGENE P. STONE, U. S. N., who died recently at North Sutton, N. H., was a native of Boston. He received the degree of M.D. from the Harvard Medical School in 1886, and subsequently entered the United States Naval Medical Service, where he became surgeon and had served at the Charlestown Navy Yard, at Annapolis and in the Naval Hospital at Manila, P. I. He is survived by his widow and two sons.

DR. GEORGE BRINTON WILSON, who died on October 1, at Chelsea, Mass., was born at Kittery, Me., on June 17, 1863. He received the degree of M.D. from the Dartmouth Medical School and subsequently from the University of Pennsylvania, and was appointed to the United States Navy Medical Corps on February 1, 1889. He sought active service in the Spanish-American War and was for several years fleet surgeon of the Asiatic Squadron. On June 1, 1912, he was appointed medical director and commandant of the United States Naval Hospital at Chelsea.

DR. STOCKBRIDGE P. GRAVES, who died on October 12, at Saco, Me., was born at Topsham, Me., in 1826. He was graduated from the New York Homoeopathic Medical College in 1866, and was the oldest homoeopathic practitioner in Saco and Biddeford, Me.

DR. ARTHUR L. HUNT, who died of anterior poliomyelitis, on October 8, in Washington, D. C., was born at Lewiston, Me., in 1877. He received the degree of A.B. from Bowdoin College, and studied medicine in Washington, D. C. After practicing for a time in that city, he became an inspector for the Health Department of the District of Columbia. In this capacity, he had exercised supervision over cases of poliomyelitis during the recent epidemic. He is survived by his widow.

DR. WILLIAM APPLETON MURKITT, F.R.C.S., who died recently in Massingham, Norfolk, England, was born at Philadelphia in 1817. He obtained his medical education in London and Edinburgh, and subsequently became a naturalized British subject. He specialized in abdominal surgery and was formerly

consulting surgeon of the Samaritan Hospital. He retired from active practice several years ago. He is survived by two daughters and one son and by his widow, who was Miss Caroline Green, a niece of Dr. Samuel A. Green of Boston.

DR. MATTHEW WOODS, who died recently at Philadelphia, was born in Ireland in 1849. After obtaining his preparatory education in that country, he migrated to the United States shortly after the outbreak of the Civil War, and served for over three years in the United States navy. He received his medical degree from the University of Pennsylvania, and subsequently became a practitioner in that city. He was a member of numerous medical and scientific societies and was the author of several monographs on epilepsy. He is survived by his widow.

DR. JAMES J. O'BRIEN, who died recently at Somerville, Mass., was born in that city on June 24, 1873. He was graduated from the Harvard Dental School in 1901, and was for several years instructor in extraction and anesthesia. He was a member of the Harvard Odontological Association. He is survived by his widow, one daughter and two sons.

#### SOCIETY NOTICES.

**SUFFOLK DISTRICT MEDICAL SOCIETY.**—A stated meeting of the Suffolk District Medical Society, in conjunction with the Boston Medical Library, will be held at the Library, on Wednesday, October 25, at 8.15 P.M.

The meeting will be a symposium in consideration of Workmen's Accident and Sickness Insurance in their Relation to the Medical Profession. There will be papers by Dr. F. J. Cotton of Boston, Mr. John P. Mead of Brockton, Dr. W. H. Merrill of Lawrence, and Dr. F. D. Donoghue of Boston.

**NORFOLK DISTRICT MEDICAL SOCIETY.**—A stated meeting of the society will be held at the Norfolk State Hospital, Wrentham, on Tuesday, October 31, at 4 P.M.

Members may go by automobile from Forest Hills Square by Washington street, through Dedham, Norwood and Walpole. Distance, about 20 miles from Forest Hills Square to Wrentham.

#### PROGRAM OF MEETING.

William H. Prescott, M.D., "The History of the Norfolk State Hospital."

Irwin H. Neff, M.D., "Alcoholism from a Medical Viewpoint."

Frank H. Carlisle, M.D., "The Drug Treatment of Morphism."

The Sessions will meet on November 9, at 2 P.M., for the examination of candidates.

BRADFORD KENT, M.D., *Secretary*.

**MASSACHUSETTS MEDICAL BENEVOLENT ASSOCIATION.**—The annual meeting will be held at the Boston Medical Library on Thursday, Oct. 26, 1916, at 5.30 P.M. The Council will meet at the same place on that date at 5.15 P.M.

GEORGE B. SHATTUCK, M.D., *President*. ROBERT M. GREEN, M.D., *Secretary*.

#### NOTICES.

**SUFFOLK DISTRICT MEDICAL SOCIETY, CENSORS' EXAMINATION.**—The censors of the Suffolk District Medical Society will meet to examine candidates for admission to the Massachusetts Medical Society at the Boston Medical Library, 5 The Fenway, on Thursday, November 9, at 4 P.M.

Candidates, who must be residents of the Suffolk District or non-residents of Massachusetts, should make a personal application, at least three days before the examination, to the Secretary, at 355 Marlborough street, between 4 and 5 o'clock, P.M. (except Saturdays and Sundays), and present their medical diplomas.

DAVID CHEEVER, *Secretary*, Suffolk District Medical Society.

### RELATION OF THE DEEP CUL-DE-SAC TO PROLAPSE OF THE RECTUM AND UTERUS, AND TO RECTOCELE.\*

BY DANIEL FISKE JONES, M.D., BOSTON.

THE difficulty of curing a disease is generally in proportion to the number of "cures" for it, and prolapse of the rectum is no exception to this rule. Few surgical conditions are less satisfactory to treat, as will be seen by looking over the records of the operated cases.

Before taking up the subject it will be well to state that this paper does not consider the cases under ten years of age, as I believe the problem is quite different in children than in adults. The term "prolapse" in this paper is intended to include those cases only in which there is a protrusion into or through the sphincter of the whole rectal wall.

It might be stated at this time also that I have practically nothing new to present in this paper; I am simply bringing to your attention facts already stated to which little or no attention has been paid. For about a year before Moschevitz' article came out in 1912, I thought that I had made a discovery. In his paper, Moschevitz intimates that he thought he was getting out something original, but found that Waldeyer, Ludloff, Zuckerkandl, and others had described very accurately the pathological anatomy of the condition, and that Bardenheuer in 1902, and Quénu and Duval in 1909 had published operations very similar to the one he advocated.

If the operations devised for the cure of prolapse of the rectum are taken as evidence, little notice was taken of the work of Zuckerkandl, Ludloff and others, up to the time of Bardenheuer's operation in 1902, as practically all the operations were devised for the purpose of tightening up the sphincter and levators, and narrowing the anal canal so that the prolapse could not get through it. It is a fact that the sphincter and levators are stretched and relaxed to a marked degree in all these cases. That this is not the cause of the prolapse can, I think, be easily demonstrated by an examination of any case in which the prolapse has been held reduced for a few weeks or months, for in these cases the sphincter and levators have regained a normal tone, and are as taut as in any normal individual.

To get a different conception of prolapse of the rectum, let us go back to the work of Zuckerkandl in 1890, Waldeyer in 1899, and to Dix, Ludloff, and others. The idea of these men, based upon anatomical findings, that prolapse of the rectum is a hernia through the sphincter, seems to have made little impression, as Bardenheuer in 1902 was, so far as I can find, the first to make use of the idea. To run over very briefly the work of Zuckerkandl, Moschevitz, and Williams, will be necessary to an understanding of the condition.

The normal pelvis in the male shows a posterior cul-de-sac which reaches to the 2d or 3d sacral vertebra. In multiparae the depth of the cul-de-sac is on a level with the posterior portion of the vaginal vault (Zuckerkandl). In males it reaches just about to the top of the seminal vesicles (Zuckerkandl).

The transversalis fascia, which lines the abdominal cavity, is continued into the pelvis

\* Read at a meeting of the Boston Surgical Society, March 6, 1916.

fascia where it gives support to the pelvic organs. Bardeleben shows this fascia as extending backward in front of the bladder, upward between the bladder and rectum, surrounding the structures at the base of the bladder, then running backward around the rectum to the posterior layer of pelvic fascia.

Williams says, "The pelvic fascia, from its attachment at the brim of the pelvis, sweeps downward and inward to the bladder, with which it is intimately connected, and to the vagina which it splits to enclose, uniting with the fascia from the opposite side, and is attached to the cervix uteri, where it helps to form the vaginal vault. This forms a strong fibrous sling which is the main support of the bladder, and the strongest of the uterine supports. The posterior portion of the fascia is deeper than the anterior, and passes downward and inward to the rectal wall to which it is intimately attached. Posterior to the rectum it covers the pyriformis and is continuous above with the anterior lamella of the lumbar fascia." It is this fascia which Williams says is the support of the uterus, vagina, and bladder. It is, we believe, this fascia which limits the depth of the posterior cul-de-sac. It is this fascia, called by various names in different parts of the abdomen, which has particularly to do with herniae, according to Moschevitz' view. It is behind all vessels and there is a more or less funnel-shaped prolongation onto every vessel, and every organ leaving the abdomen or pelvis. It is this fascia which supports the pelvic organs and the floor of the posterior cul-de-sac. It is a defect in this fascia, the absence of it, or the stretching of it which is responsible for the extension of the cul-de-sac downward to the levator muscles. Zuckerkandl states that a deep posterior cul-de-sac is essential to the formation of perineal, rectal, and vaginal herniae. The manner of formation of the deep cul-de-sac is of interest. It is, we believe, either congenital or acquired.

Zuckerkandl, Freund, and others have shown that this cul-de-sac normally extends to the levators in the foetus, and that the depth is gradually decreased from this time to puberty, when it reaches to the level of the 2d or 3d sacral vertebra.

Moschevitz believes that the fascia is normally attached to the rectum by a funnel shaped extension downward on to it. A defect in this attachment allows the intestines to push downward along the rectum to the levators. The defect, he believes, to be congenital but the sac or deep cul-de-sac is acquired.

Another acquired form is that found in multiparae, due to the stretching of the peritoneum and fascia.

Clinically, there are three distinct varieties of deep cul-de-sac. The first is the variety which we distinguish as congenital, in which the peritoneum lining the deep pelvis is smooth and

closely adherent to the walls of the pelvis and to the rectum and vagina or bladder; the rectum instead of standing out as a definite organ is usually flattened against the sacrum and coccyx, and scarcely distinguishable from the peritoneum. The bladder in males, instead of being a rounded organ occupying the central portion of the pelvis, is flattened posteriorly and at the base, and extends from one side of the pelvis to the other. There is absolutely nothing to indicate the depth of the normal cul-de-sac. This variety is found in the cases of prolapse of the rectum in males and virgins, and in prolapse of the uterus and vaginal herniae in virgins. I have rarely seen a deep pelvis of this form in which there was not either a prolapse of the rectum or uterus, or a rectocele.

In the second form, which we have called the acquired variety, the cul-de-sac is deep, but does not appear so deep as in the first; the peritoneum is redundant and is not adherent to the pelvic walls, rectum and vagina, or bladder. The rectum, instead of being flattened against the posterior wall, stands out distinctly in the pelvis. This form is of frequent occurrence in multiparae, yet the occurrence of prolapse of the rectum is very rare, while prolapse of the uterus and large rectoceles are infrequent in proportion to the number of cases of this acquired deep cul-de-sac.

The third variety is very rare; in these cases there is a small opening between the vagina and rectum reaching from a posterior cul-de-sac in normal position down to the levators, and usually causing a vaginal protrusion. The appearance of this variety would suggest a defect in the posterior portion of the pelvic fascia, through which the intestines had forced their way to the depths of the pelvis. The comparatively small opening with a distinct floor of the posterior cul-de-sac at its normal height suggests the protrusion through a small defect in the fascia, as suggested by Moschevitz as the cause of the deep cul-de-sac, and exactly analogous to the formation of an inguinal hernia.

We have for some time tried to find an explanation of the large proportion of prolapses and vaginal herniae in the first group, that is, congenital variety, as compared with the small proportion found in the second group, that is, acquired variety.

It is our belief that there is not only a congenitally deep cul-de-sac, but that there is an absence of fascia lining the cavity in the congenital group, while in the second group the fascia is stretched by the gravid uterus and childbirth sufficiently to allow the peritoneum to sink into the depths of the pelvis but still leaves it attached to the vagina and rectum. In the first group there is no fascia, the constant pressure of the intestines is against the levators, anterior wall of the rectum and posterior wall of the vagina, and as muscle fibres will not stand a long continued pressure without

stretching, these parts soon give way, and are pushed through the sphincter or out through the vulva. In the second group the fascia, while stretched and thinned, is sufficiently strong to take the strain without stretching. As the anterior rectal wall is stretched downward against the sphincter, they both must give more and more until the rectal wall pushes through the sphincter. The prolapse, when first formed, is always the anterior rectal wall, and as this progresses, the posterior wall is loosened sufficiently to be pulled down also. In place of the rectal wall giving way, the posterior vaginal wall may be stretched, and we have either a rectocele, so called, or a vaginal hernia.

In regard to rectoceles, we believe that there are two distinct conditions which are designated as rectocele. In virgins, the rectocele is always a protrusion of the posterior vaginal wall caused by the intestines in the deep posterior cul-de-sac pushing the wall forward and downward, that is, it is a hernia. The rectum has nothing whatever to do with it, except that the rectum is pulled downward by the lower portion of the posterior wall as it is everted.

In some multiparae with badly torn perineum, and stretched posterior wall of the vagina, we have what may be called a true rectocele, that is, the rectum, having no support anteriorly, bulges into the vagina. The bulging increases very little, because the intra-rectal pressure can be little more than the normal.

The second variety occurs in those cases in which there is a deep posterior cul-de-sac; the intestines force their way downward between the rectum and vagina, and push the posterior wall of the vagina forward and downward. It is, therefore, the intestines in this cul-de-sac which are bulging into the vagina, and not the rectum. If the surgeon after doing a perineorrhaphy on a well-marked case of "rectocele," will open the abdomen and examine the posterior cul-de-sac, he will easily feel his sutures at the lower end of the cul-de-sac, and will still be able to push the posterior wall of the vagina forward over them.

Little has been said of prolapse of the uterus in these conditions of deep posterior cul-de-sac. The uterus is suspended by the anterior portion of the pelvic fascia to some extent, so that even with the loss of support of the posterior portion the uterus does not prolapse at once. The constant pressure of the intestines on the posterior vaginal wall, not only pushing it forward, but forcing it downward toward the vulva, at the same time exerts a considerable pull upon the uterus; this, in addition to the loss of support of the posterior fascia, causes prolapse of the uterus in many cases. It is probable also that the anterior fascia is defective in those cases in which the posterior portion is thus aiding in the prolapse.

It has been my good fortune to see four vir-

gins within the last two years with what I believe to be a congenital deep posterior cul-de-sac. The condition in the pelvis was identical in all. In one there was a prolapse of the rectum, in another there was a prolapse of the rectum, a large "cystocele" and a prolapse of the uterus. In two others there was a "rectocele" and a prolapse of the uterus.

Granted then that prolapse of the rectum, rectoceles, and prolapse of the uterus are caused by deep posterior cul-de-sac and are really herniae, what is the proper treatment for them? For prolapse of the rectum the operations which have been done may be divided into three groups.

1. Those which attempt to prevent the prolapse by supporting the outlet of the pelvis or by narrowing the outlet.

2. Those which attempt to prevent the prolapse by fixation of the bowel above or bring about the same result by amputation of the prolapsed portion.

3. Those which not only suspend the bowel but close the hernial sac at what might be called the internal ring.

Let us consider these operations in groups to save time, taking up only a few special operations; and let us admit for the sake of argument that prolapse of the rectum and uterus are herniae; and we must admit that they are at the time they become fully developed prolapses, whether we believe that the deep cul-de-sac is the cause or the effect of the prolapse.

In the first group we put those operations which attempt to prevent the prolapse or hernia by narrowing the outlet or by supporting the perineum. The evident fact in cases of prolapse is the dilated and atonic sphincter, and a relaxed perineum. The obvious thing to do, therefore, is to tighten up the sphincter, and give more support to the perineum.

In comparing this group of operations with an inguinal hernia, it is evident that the placing of a band about the sphincter is almost exactly similar to closing of the external ring by a suture. Undoubtedly this will hold up a certain number, and so will closure of the external ring prevent a certain number of inguinal herniae from protruding.

The support given to the perineum is similar to tightening up the external oblique fascia, without removing the sac, and this, of course, means a recurrence.

The Tiersch operation of placing a silver wire about the anus is undoubtedly of value in very old or very feeble patients.

The Delorme-Juvara operation of removing a collar of mucous membrane apparently gives excellent results, comparatively speaking, but there is some danger about it. 67% mortality according to Delorme, and the end results, while excellent, according to Delorme, are not sufficiently good to consider it the operation of

choice. Quénu considers it an excellent adjunct to the abdominal operation.

In the second group we have operations which might be compared to pulling the hernial sac up as far as the external ring, and leaving it open above. While most of these operations do give support to the rectum for a time at least, they overlook a very important fact, that is, the rectum at its lower segment has been so stretched by pressure upon it that no amount of pull above will take up the slack here. Besides that, the intestines are free to continue their pressure upon the anterior wall, and ought, in time, to reproduce the prolapse, if it does not immediately.

It will be seen, then, that according to our estimate at least, the operations in Groups 1 and 2 are, at least theoretically, wrong. We must, therefore, find some operation which will be more satisfying, at least theoretically.

In 1912, after a recurrence following the so-called Tuttle posterior rectopexy, and having a patient transferred to me with a recurrence following the same operation done by a colleague, I determined to do a colopexy. The first thing which struck me when I opened the abdomen was the great depth of the pelvis: there was no posterior cul-de-sac at all, the pelvis to the levators was wide open, the rectum was flattened against the sacrum, and the peritoneum evidently rested upon the levators: the sphincter could be easily felt from the cul-de-sac. An attempt was then made to pull the rectum into place by pulling upon the sigmoid, in preparation for a colopexy, but to my surprise I found that a pull upon the sigmoid pulled upon the attachment of the rectum only, and did not pull upon the lower three inches of the rectum itself.

The next patient was a male, and the pelvis presented a most extraordinary appearance. The depth of the pelvis was most striking; it also had the appearance of having no organ in it, for the rectum was flattened out against the posterior surface, and was not easily distinguished from the peritoneum. The bladder, which is ordinarily a rounded organ, had a flattened base, which extended from one side of the pelvis to the other. The seminal vesicles and prostate were pelvic organs, that is, in the portion lined by peritoneum.

As colopexy seemed to offer no hope of curing these patients, an effort was made to restore the cul-de-sac to its normal appearance, by closing it with purse-string sutures of silk; in addition to this, the rectum was attached to the pelvic peritoneum on either side, as high as the promontory, by silk sutures, in the hope of getting support from many attachments to the peritoneum.

In the female, in addition to closing the posterior cul-de-sac, the rectum was sutured to the posterior surface of the vagina and uterus, and a ventral fixation done.

It is true that in closing the posterior cul-de-

sac, in this way, one is probably suturing nothing but peritoneum, and therefore does not feel that the results can be very permanent. It is very necessary, therefore, to make every effort possible to prevent recurrence. In our cases the posterior cul-de-sac was closed and the rectum attached to the pelvic peritoneum as high as the promontory. Moschcovitz simply closes the cul-de-sac.

Bardenheuer closed the posterior cul-de-sac and attached the mesentery of the rectum to the pelvic peritoneum from right to left.

Quénu and Duval closed the posterior cul-de-sac, then sutured the rectum to the posterior surface of the bladder or vagina on the right, then across to the left side of the pelvis, where a slit was made in the peritoneum over the psoas, and the sigmoid sutured to the edges and to the iliac fascia beneath. The value of this procedure is, we believe, overestimated by them, as it is impossible for the sigmoid sutured in this way to exert any pull upon the lower portion of the rectum. It is, we believe, an excellent way of making the closure of the cul-de-sac more sure.

Quénu states that other operations, such as the Delorme-Juvara, or the Tiersch, may be necessary adjuncts to their operation.

It is, we believe, important in many of these cases, especially the large prolapses, to do something else than closure of the cul-de-sac, to aid in the support. At times removal of mucous membrane with the cautery will assist. In many we are convinced that posterior rectopexy will be of great value. While the giving way of the posterior attachment is not the cause of prolapse, the posterior attachments are loosened and pulled down late in the course of the prolapse. Fixation, therefore, of this portion of the rectum must be of some value in holding up the rectum.

In closing the posterior cul-de-sac, it must be remembered that the anterior wall of the rectum is well stretched, and in order to prevent this portion from prolapsing, it must be drawn well up in the pelvis by a guide suture placed as low as possible into the rectum, and this portion fixed as high as possible. While the dangers of closing the posterior cul-de-sac, that is, injury to the ureters and to the great vessels, may seem considerable, we have had no complication in about twenty cases.

As to the operation for rectocele and prolapse of the uterus, the operation is identical in every detail to that for prolapse of the rectum. We do not believe it necessary or advisable to do an abdominal operation for every rectocele, for our present methods are satisfactory. In large rectocele, and in smaller ones, when the abdomen is opened for some other purpose, the closure of the cul-de-sac is rational, and we believe, essential, to prevent recurrence in many cases.

In all cases of prolapse of the uterus in virgins, there is, we believe, a deep posterior cul-

de-sac of the congenital type. What other conditions there are to cause the prolapse, we do not know. The rational procedure in these cases would seem to be closure of the deep cul-de-sac, the one condition present in all cases, in addition to ventral fixation. Not only do we believe this essential for the permanent cure of these cases, but we believe it necessary to prevent prolapse of the rectum or vaginal hernia later in life.

W. A. Freund, recognizing the relation of the deep cul-de-sac to prolapse, inverted the uterus into the cul-de-sac and sutured it to the sacrum.

In cases of prolapse of the uterus in multiparae, while we believe that stretching of the fascial supports has more to do with prolapse than deep cul-de-sac, we believe that closure of the cul-de-sac will lead to much better results. If the operator will make pressure downward in the cul-de-sac against the posterior wall of the vagina, he will see at once the great pull which can be exerted upon the uterus. If he will then close the posterior cul-de-sac and make pressure upon that, he will, we are sure, be convinced as to the value of closing the cul-de-sac in these cases. If one does not believe in its efficacy in prolapse of the uterus, the closure should be made to prevent the possibility of prolapse of the rectum and posterior vaginal wall.

While closure of the posterior cul-de-sac by purse-string sutures may seem to have little strength, its great value lies in the fact that the closure throws the weight of the intestines forward onto the bladder, symphysis, and anterior abdominal wall, when the patient is in the upright position, as pointed out by Dr. Edward Reynolds, while the deep cul-de-sac allows the weight of the intestines and pressure to come upon the anterior rectal wall or posterior vaginal wall.

---

## THE EFFECT OF ALCOHOL IN THE RATE OF DISCHARGE FROM THE STOMACH.

By L. T. WRIGHT, M.D., ATLANTA, GA.

[From the Laboratory of Physiology in the Harvard Medical School.]

THE methods employed to determine the rate of discharge of the gastric contents into the intestine have in the past been so unreliable that judgments based on them are not worthy of great credence. The results have been expressed in terms of "gastric motility," a rather vague expression which properly means the activity of the stomach wall in muscular contraction. Gastric peristalsis is only one of the elements of gastric discharge, however, because peristalsis is

obviously ineffective if the pylorus is held tightly closed. Thus there may be a high degree of "gastric motility" with no discharge, as, for example, in pyloric stenosis. In spite of its rather loose employment, the term "gastric motility" has probably in most instances been intended to signify the efficacy of the stomach as an organ discharging its contained food.

Some previous observers have stated that alcohol in "moderate" doses increases gastric motility, whereas greater quantities or concentrations have the opposite effect. This is the testimony, for example, of Klemperer<sup>1</sup> and of Kast.<sup>2</sup> Others have declared that its influence is solely as a depressant,<sup>3</sup> and still others have claimed that it has a stimulating effect.<sup>4</sup> Because of these differences of testimony it seemed worth while to seek further evidence regarding the effect of alcohol in the rate of gastric emptying.

The method used was that first devised by Cannon.<sup>5</sup> Its reliability has been substantiated by other investigators, especially by workers in Magnus's laboratory of pharmacology in Utrecht. In brief, the procedure was as follows: Medium sized, quiet cats, deprived of food for 24 hours, were fastened to a holder and fed through a stomach tube attached to a syringe, 25 cc. of mushy potato to which had been added 5 grams of bismuth subcarbonate. If the cats had eaten within 24 hours before the feeding, the rate of discharge was apparently slowed. Fully 25 cc. should be given at each feeding—an amount which causes the stomach in most cats to cast about the same size of shadow. In a few animals the stomachs seemed dilated; and 25 cc. of the potato-bismuth mixture left light areas here and there, as if the organ was not filled. Both peristalsis and the rate of discharge in these animals, however, were normal. The consistency was, so far as possible, uniform—the potato was mashed till of fine, soft consistency and then made mushy by the addition of water, and also of alcohol.

After being fed the animal was immediately released. X-ray observations of the gastric and intestinal shadows were made first at the end of a half-hour, then at the end of an hour, and thereafter hourly until four hours after the feeding. All observations were fluoroscopic, but records were made by tracing on translucent paper the shadows of the intestinal contents. As explained by Cannon, with proper precautions to avoid overlapping of shadows, and with due care in making the tracings accurate, the aggregate length of the shadows in the successive records may be utilized to indicate the rate of gastric discharge.

I first tested the method and accuracy of it by making observations on six cats fed the potato-bismuth mixture, and then the addition of alcohol. The following figures represent the aggregate length of the shadows of the food masses in the small intestine in these cases at the times indicated, are the results secured:

Hours After Feeding.	$\frac{1}{2}$	1	2	3	4
March 6—Cat 1....	12.5	24.0	41.5	20.0	13.5
March 6—Cat 2....	11.0	23.5	38.0	18.5	11.5
March 25—Cat 3....	19.5	25.0	41.2	24.5	18.0
March 25—Cat 4....	10.7	27.5	37.4	30.0	23.0
March 25—Cat 5....	17.0	22.4	39.0	24.0	19.5
March 25—Cat 6....	14.0	29.0	42.0	40.0	35.0
Average.....	14.0	24.2	39.5	26.	20.

No more than six cats were observed in this test series because the figures from the different animals agreed so well and because the average figures obtained by me were so near those obtained by Cannon (14, 24, 39.5, 26, and 20 cm. as compared with Cannon's 10, 31, 42, 25, and 21.)

In the experiments with alcohol the commercial 95 per cent. alcohol was employed, though in some of the tests a lower percentage (37 per cent.) was made by dilution with distilled water. In order to avoid loss by evaporation the alcohol was always added to the potato-bismuth mixture just before it was fed to the animals. It was added in two strengths—6 cc. of 37 per cent., and 5 cc. of 95 per cent. The latter combination was less cohesive than the former, and there was a tendency for fluid to separate out from it. It was stirred thoroughly just before being put in the syringe, and the syringe was emptied at once.

The weaker mixture (6 cc., 37 per cent., or about 0.7 cc. per kilo) produced no striking symptoms. There was occasionally a slight unsteadiness in the feet, or perhaps some increase in irritability, as manifested by greater excitement while on the holder and under observation. But this was hard to judge. The stronger mixture (5 cc., 95 per cent., or about 15 cc. per kilo) rapidly caused extreme intoxication. A staggering gait, which appeared soon after the feeding, was followed by quietness, and later, after an hour or two, by stupor. The stupor was accompanied by shallow and, as a rule, slow respiration. In no case did an animal die from the intoxication.

The rate of passage from the stomach of the potato-bismuth mixture to which 6 cc. of 37 per cent. alcohol had been added is shown by the following figures and also graphically by the dashline in Fig. 1:

Hours After Feeding.	$\frac{1}{2}$	1	2	3	4
March 4—Cat 1....	22	38	62.5	50	38
March 11—Cat 2....	22.5	39	49	45.5	34.5
March 11—Cat 3....	25	39	58	45.5	43.5
March 17—Cat 4....	18.5	34	48	39	28.5
March 17—Cat 5....	20	28	48	37.5	37.5
March 17—Cat 6....	19	35	48.5	36.5	33
Average.....	21	35.5	52.5	42.5	36

Like the normal records for mashed potato these records show a maximal number of centimetres of the food in the intestines at the end of two hours, but the maximum number is 52.5 instead of being in the neighborhood of 40 cm. The increase is notable even at the end of a half hour; 21 cm. is 50 per cent. higher than the

average figure for normal conditions (14 cm.), and the figure for an hour is likewise about 50 per cent. above the normal. This relatively small amount of alcohol, therefore, has distinctly an accelerating effect on the rate of gastric discharge and produces a higher maximum than the normal.

I noticed that the gastric peristaltic waves were deep and vigorous. In most cases at the end of three hours no residue remained in the stomach.

When the stronger alcohol (5 cc. of 95 per cent.) is added to the potato-bismuth mixture the aggregate length of the food-masses in the intestines at the times designated was as follows (see also the dotted line, Fig. 1):

FIG. 1.

Hours After Feeding.	$\frac{1}{2}$	1	2	3	4
March 9—Cat 1....	0	0	25.5	26.5	43
" 2....	4.5	20	22	28.5	29
" 3....	3	5.5	23.5	40	44
" 4....	0	16	38.5	46.5	45.5
April 3 " 5....	0	0	0	15.5	25.5
" 6....	0	6.5	22.5	32	29
" 7....	0	0	28.5	47	38
April 10 " 8....	0	14	23.5	41	43
" 9....	0	12	28.5	40	43
" 10....	12	17	23	39	50
" 11....	0	6	27	50	45
Average.....	2	9	24	38	39.5

As the figures show, eight of the eleven animals reveal no gastric discharge at the end of a half-hour, and in three nothing had left at the end of an hour. In four other cases on which observations had to be stopped because of a breakdown of the apparatus, three had no gastric discharge at the end of a half-hour, and the fourth had only 5.5 cm. of intestinal content. There is a good deal of variation in the different cases, but the average figures show a slow initial discharge and a gradual rise to a maximum at the end of three or four hours.

These results are in contrast to those obtained either under normal conditions or after giving a smaller amount of alcohol (see Fig. 1). Peristaltic waves when evident were shallow and feeble, and in some of the animals there was present in the stomach at the end of four hours a considerable amount of food.

Cannon has brought forward evidence that gastric discharge is normally dependent on the development of an acid reaction in the contents near the pylorus and a subsequent interplay between effects of acid on either side of the pylorus, acid on the stomach side opening and on the duodenal side closing the orifice.<sup>1</sup> It has been observed that moderate amounts of alcohol stimulate the secretion of gastric juice.<sup>2</sup> The more rapid expulsion of gastric contents when the weaker alcohol was used may have been due not only to a more vigorous peristalsis, but also to a more prompt acidulation of the contents. The retardation of the output when the stronger alcohol was employed was likewise, in all probability, due to effects on both peristalsis and secretion. The profound influence of the stronger alcohol on the central nervous system indicates that the nerves of the gastric wall, and possibly also the muscle fibres, were similarly affected, and the weakness of the peristaltic waves (when any were seen) supports that supposition. Pavlov has shown that strong alcohol causes an abundant secretion of mucous, neutral or faintly alkaline in reaction.<sup>3</sup> On the basis of an acid control of the pylorus, therefore, as well as on the assumption of an intoxication of the gastric neuromusculature, it is easy to understand how the stronger alcohol mixed with the food produced so marked a slowing of gastric discharge as was seen in these observations.

## BLOOD TRANSFUSION IN THE GREAT WAR.\*

By WILLIAM REID MORRISON, M.D., BOSTON,

*Assistant in Anatomy, Harvard Medical School.*

[From the Twenty-second General Hospital, British Expeditionary Force, France, Harvard Second Surgical Unit.]

IN military, as well as in civil surgery, blood transfusion holds an important position. It is accepted by most surgeons to be the best treat-

ment for hemorrhage and surgical shock. I wish to emphasize the value of blood transfusion in severe secondary hemorrhages, associated with septic gunshot wounds, so commonly seen in military surgery.

During our service at this base hospital in France, several severe secondary hemorrhages were encountered, usually from infected shrapnel wounds of the extremities.

These patients had lost a good deal of blood, at the time of the initial injury, and as a result, had a low percentage of hemoglobin. They presented the pale, sometimes yellowish color of anemia, with the anorexia and general debility which would be expected in such cases. The temperature was subnormal, or slightly elevated, with more or less rapid pulse, of poor quality and volume, due to lowered blood pressure.

Secondary hemorrhages often occurred spontaneously, or on the removal of gauze packing in wounds near, or involving the main blood vessels. After repeated losses of blood, particularly in amputations of the arms or legs, the patient's blood appeared very watery, not tending to coagulate. The granulation tissue was very pale and boggy, all the more so when hypochlorous solution was used as a dressing. The bleeding point sometimes could be snapped, and tied, more often a general, continuous ooze persisted, despite gauze packing.

Severe hemorrhage repeatedly occurred from the use of more or less rigid, large, rubber drainage-tubes, which had been put in at the front, either spontaneously, from erosion of the blood vessel walls, or on the removal of the drain. Large, pliable, cigarette wicks of gutta-percha tissue, wrapped around gauze, were mainly used by us, for drainage, in these infected wounds, involving areas where there were blood vessels of any size.

The general routine treatment for shock and hemorrhage was carried out; the patient was kept warm with heaters and blankets, while morphine sulphate, one-quarter of a grain, subcutaneously, every four hours, as needed, obtained rest and quiet. The foot of the bed was elevated, if the pulse was high. If there was no vomiting, nourishment in the form of eggnogs, custards, milk, champagne, or the less valuable soups, meat extracts, etc., was prescribed freely. In case of nausea, enemata of twenty per cent. glucose, of six ounces each, were given.

Normal salt solution, in lieu of blood, or in conjunction with blood transfusion, may be given subcutaneously, usually under the breast, although the intravenous method is quicker. This raises the arterial tension, and replaces the lost fluids of the body tissues. Too much fluid should not be injected, because it may overtax the heart; furthermore, salt solution does not increase the coagulability of the remaining blood. Rectal tap water may be given drop by drop, or in the form of enemata.

Many of the English medical officers insisted

\* Read at a meeting of the East Boston Medical Society, September 29, 1916.

that blood transfusion had no advantages over normal salt solution, and they placed much stress on the possible occurrence of hemolysis, and the transmission of venereal, or other disease, to the recipient.

Any of the many hemolysis tests may be made, if one has the available time and apparatus. If the result is negative, well and good; but if positive, hemolysis may occur, although it must be borne in mind that the test is made under very abnormal conditions, and the reverse of the test may take place in the body.

The Wassermann test, with a negative history and physical examination, may rule out syphilis, but in our hospital, few patients had had a Wassermann test, because convoys were coming and going continually, so that there was little time or opportunity to make them.

The following typical emergency cases had neither hemolysis or other blood tests made, on account of lack of time and facilities. Healthy-looking donors, who denied having had venereal, or other disease, were accepted, and small amounts of blood were transfused by the indirect, vein to vein method. The Kimpton-Brown two hundred and fifty cubic centimeter glass tubes were used, coated with Vincent's stearin, paraffin and vaseline mixture, consisting of one part of stearin to two parts each of paraffin and vaseline.

If the patient shows no evidence of hemolysis, repeated half-pint doses may be given.

Sterile water or normal salt solution may be used as a coating for the tubes, but the clotting of blood is delayed much longer by the paraffin mixture.

Blood transfusion was done in the following case, both for repeated hemorrhages and to enable the patient to stand the shock of amputation.

Lance Corporal G. F., 2765, of the Fourth Gordon Highlanders, twenty-two years of age, was admitted to the Twenty-second General Hospital on May 3, 1916. He received multiple gunshot wounds of the right leg, on May 1, 1916, while in the front line trenches, and on transfer to the Casualty Clearing Station, he collapsed from loss of blood and shock. The femoral artery and vein were tied off, just above Hunter's canal, where they were injured. On May 3, 1916, he was transferred to the ambulance train, and admitted to this hospital at 10.30 p.m., in Ward A2.

May 4, 1916. Dressings removed, and septic lacerated wound eight inches long on inner aspect, right upper leg, found packed with gauze. Similar deep wounds six inches long, on anterior and posterior aspects of right lower leg, also packed with gauze. The gauze was removed from the wound of the upper leg, and chlorinated soda dressing applied. The packing was removed from the wounds of the lower leg, resulting in profuse hemorrhage from both wounds, not controlled by packing. The anterior and posterior tibial arteries were tied, after enlarging the wounds, and a chlorinated soda dressing applied. Eighteen ounces of normal salt solution were given subpectorally.

Multiple septic shrapnel wounds of the back and loins were dressed with chlorinated soda solution.

The general physical examination was negative, except for marked anemia.

May 5, 1916. Right leg cold, evidently no circulation of blood. General condition poor. Urine negative. Patient takes fair amount of nourishment.

May 6, 1916. Right leg blue, mottled, cold. No pulsation of dorsalis pedis artery. Wounds very septic, discharge foul, despite frequent dressings. It was thought advisable to amputate at mid-thigh, by the surgeon-in-chief, Dr. W. E. Falkner.

With his consent, in order to combat shock, and prevent further bleeding, two hundred and fifty cubic centimeters of blood were transfused by me from Private S. H., a bomb-thrower of the Twelfth King's Liverpool Regiment, who generously offered his blood for his comrade.

Local anesthesia, with one-half per cent. novocain, was used, after the antecubital fossa and surrounding skin had been shaved, scrubbed with soap and water, and alcohol. One inch of the median basilic vein of both donor and recipient was isolated by blunt dissection with scissors, after incision of the skin along the anesthetized area. Two strands of catgut were slipped under the vein of each patient, one to control the flow of blood, and the other to tie off the vein, proximally for the donor, and distally for the recipient.

We do not like to use a tourniquet, as the assistant may forget to remove it, in which event no blood can be forced past it.

The veins are opened by sharp scissors, or knife, cutting half way through them, the flow of blood being controlled by an assistant lifting gently on the catgut strand. A gauze sponge, moistened with salt solution, is placed over the recipient's wound, until the blood is transferred from the donor. The sterilized tubes, coated with the aid of an alcohol lamp, or Bunsen burner, with the paraffin mixture in aseptic hands, is inserted in the donor's vein pointed away from the heart. His blood pressure, aided by flexing and extending the fingers, fills the tube with blood. If difficulty is experienced in inserting the tube, small right-angled forceps or little hooks make useful vein openers. If the blood does not flow readily, altering the position of the tip of the tube facilitates the flow, for the tip may be pushed against a valve in the vein, or against the vein wall too tightly.

When the desired amount of blood is in the tube, it is removed from the vein, and the assistant lifts the catgut gently, stopping further flow. Care should be taken to prevent loss of blood from the tube, by holding one finger over the cork stopper, which falls out readily if the tube is tilted to one side, and placing another finger over the right-angled branch of the tube, during transfer to the recipient. The tube is inserted in the vein toward the heart, and a sterilized cautey bulb is used to drive the blood in slowly by air pressure. Air embolism is to be avoided, by removing the tube from the vein before all the blood has been driven out. The veins are tied off doubly, and excised between ligatures, and the skin sutured.

This transfusion brought the patient's pulse down to 100, improved its quality, and gave a pink color to his cheeks.

A tourniquet was then applied to the right upper leg, and a mid-thigh amputation, by transfusion, was quickly done under primary ether. The flaps

were not sutured, the blood vessels were tied, and chlorinated soda dressing applied. One pint of salt solution was given subpectorally.

The patient withstood the shock of the operation very well, and had no more hemorrhages.

Three days after operation, he developed a virulent streptococcus septicemia, as shown by blood culture. He was given one hundred cubic centimeters of one-half per cent. Eusol solution, intravenously, without effect one way or another. He ran a septic temperature, and died suddenly on the fifth day after operation. No autopsy.

The donor of this transfusion was chosen particularly, because he had a healing granulating wound of the back, caused by shrapnel, and it was thought that his blood would contain antibodies favorable for the recipient.

The following case is a typical one of secondary hemorrhage. I demonstrated this method of blood transfusion at Canadian Number One General Hospital, on the invitation of their surgeons.

The patient, Lance Corporal W. E. S., 1288, of the Tenth Royal Fusiliers, age thirty-three, was admitted to that hospital two days previously, with amputation of the right lower leg, for gas bacillus gangrene, and gunshot wounds of the left hip and knee. He had previously had several severe hemorrhages from his wounds, and he was very anemic. Two hundred and fifty cubic centimeters of blood were transfused from Private L. J. S., 21299, of the Eighth Border Rifles. The recipient had two septic wounds of each elbow, involving the median basilic and median cephalic veins, due to salt solution being injected intravenously at the front, so we had to use the cephalic vein high up in the upper arm.

The patient's general condition was improved, and he had no more hemorrhages. Three weeks later, I saw both donor and recipient, and both were doing well. The donor in this case was admitted for bronchitis.

The blood of a member of the patient's family is preferable to a stranger's blood, but hemolysis may occur when two children of the same parents are transfused, so one need not hesitate about using a healthy stranger's blood, in small, and if necessary, repeated doses.

Hemolysis is rare, and even if it does occur, a small amount of blood, as half a pint, is not overwhelming. If no hemolysis occurs, that amount of blood may, and usually does, stop further bleeding, and under favorable conditions the dose may be repeated, if indicated.

The transfusion of blood not only tends to stop hemorrhage, but at the same time furnishes a highly concentrated form of nourishment, and in my opinion should be employed more frequently.

## UNDESCENDED TESTICLE IN CHILDREN.\*

By C. G. MIXTER, M.D., BOSTON.

THE testicle normally descends into the scrotum during the eighth month of intrauterine life. As it passes from the abdomen down the inguinal canal to the scrotum, it lies in a process of peritoneum, the processus vaginalis that becomes obliterated by fusion of its surfaces, leaving a closed sac at the lower end in which the testis lies, the tunica vaginalis. If, however, the testicle fails to descend, fusion does not take place. The undescended testicle, therefore, is accompanied by a congenital hernia. Though merely a matter of degree, the undescended testicle can be described for convenience as lying intra-abdominally, within the inguinal canal or at the external inguinal ring. The scrotum is always shrunken and rudimentary.

In performing any plastic for the relief of this condition, the essential factor is to obtain a sufficient length of cord to permit the testicle to rest easily in the scrotum without tension. It is much easier to secure sufficient length of the vas than of the spermatic vessels. For this reason complete section of the spermatic vessels has been advised by Hegan in cases where the testicle cannot be brought readily down into the scrotum. The accompanying vessels of the vas he considers will suffice to nourish the testicle.

In the past 3 years, 30 operations have been performed for the relief of this malformation at the Children's Hospital. In 7 cases the condition was bilateral; in 9, the right, and in 7, the left side was affected. In 3 cases the testis was intra-abdominal. In 19, it lay within the inguinal canal, and in 8 cases it was just outside the external inguinal ring. In 2 cases, atrophy was noticed at the time of operation. In 1, the testicle was enlarged and thought to be tubercular, and there was an accompanying tubercular peritonitis. The age at operation was: under 2 years, one case; 20 months old; between 2 and 6 years, ten cases; between 6 and 12 years, 12 cases.

The late result of operation was ascertained in 26 instances—4 cases failed to report. The two cases in which atrophy was noted at operation, showed no improvement in the development of the testicle, although the organ remained in the scrotum. There was atrophy in 8 cases following operation. Interference with the enervation of the testicle has been suggested as a cause of atrophy following operation, but nothing to substantiate this view could be deduced from the operative records of these cases. The age at operation had no bearing on the occurrence of atrophy, it being no more frequent in the younger group than in the older in this series. The one factor present in every instance where atrophy occurred, was an interfer-

\* Read at a meeting of the New England Branch of the American Urological Association, held in New York, 1915.

ence with the spermatic circulation at operation.

These cases can be divided into 3 groups; in one, all the spermatic vessels were cut at operation to facilitate the placing of the testicle in the scrotum. In the second, a portion of the lesser vessels were divided and the 3 or 4 main trunks were left. In the third, the vessels were left intact—the latter group comprises 15 operations. Of 14 cases reporting there was no occurrence of atrophy following operation. There were 5 instances of partial division of the vessels. One case did not report and in one case there was post-operative atrophy. The vessels were completely divided in 9 cases; 7 cases reported and in every instance there was marked atrophy. In all the testicle was soft and no larger than a bean. At one operation the testicle could not be brought down and was replaced within the abdomen.

There were 4 cases of bilateral undescended testicle in which section or partial section of the vessels had been performed on one side and the vessels left intact on the other side. Three reported and in every case the testis was atrophied on the side where the vessels were cut; while where the vessels were left intact, the testicle developed normally. In the fourth case the time since operation has been too short to make the observation of value.

At the risk of repeating what is already familiar to you, with perhaps the exception of certain minor points of technic, I will briefly outline the steps of the operation I have found will best conserve the spermatic vessels and give adequate length to the cord.

A liberal hernia incision is made and the external oblique aponeurosis is split. The hernia sac is separated from the cord and a tunica formed about the testicle from its lower end. The testicle should not be handled unless covered by its tunica. Trauma of the unprotected testicle is the usual cause of the excessive swelling that sometimes follows this operation. A bed is prepared in the scrotum. The hernia sac is transfixed and tied at the internal ring and excised. Traction is made by the tie on the peritoneal stump and by blunt dissection, the peritoneum covering the vessels as they pass upward and backward is freed along the posterior abdominal wall. Preferably this is done by finger dissection. By gentle pull on the testicle, the fibrous bands holding the vessels are brought into view and torn across. The separation is carried on as far as the finger can reach. All of the cremaster muscle and fibrous tissue is excised, leaving simply 4 or 5 spermatic trunks in the inguinal canal free from the vas. The latter is similarly freed from peritoneum where it turns downward and backward into the pelvis, and the transversalis fascia, whose upper margin forms a pulley over which the vas hooks, is incised downward as far as the deep epigastric artery. This will unquestionably lengthen the vas sufficiently. Should the vessels still prevent the testicle from lying without tension in

the scrotum, gentle traction on the testicle will show which of these trunks are under the greatest strain and one or two of these may be tied and cut. A temporary suture is then placed through the tunica and passed out through the bottom of the scrotum and clamped to the operating sheet to hold the testis in position during closure. Purse string sutures around the upper part of the scrotum are unnecessary. The hernia is repaired without transplantation of the cord.

During the last 3 years, I have followed this procedure in 23 operations. The testicle was brought down into the scrotum without sacrificing the spermatic vessels in 17 instances. One case has not reported, in one atrophy was noted at operation and still persists, and two operations have been done within the last month and should not be enumerated. In the remaining 13 cases there has been no atrophy and the testicle was found movable and in the scrotum at examination. In 4 instances partial resection of the vessels was done. Atrophy was found at operation in one; the condition is unchanged. Atrophy followed operation in one case. In the other two instances there has been no atrophy; the testicle having been intra-abdominal in one of these. In two cases the spermatic vessels were completely divided. I do not now consider that the procedure was essential or justifiable in these cases. Both show marked atrophy.

The results obtained in the younger children in this series were as good as in the older children, both in regard to the position of the testis in the scrotum and in the presence or absence of atrophy.

Preferably operation may be performed at any time after 3 years. Should beginning atrophy from pressure be noted, however, early operation should be advised. If the hernia gives rise to symptoms a plastic can be done in infancy and a good result may be expected.

I have considered the results in these cases satisfactory as long as there was no atrophy and the testicle remained in the scrotum, without attempting to differentiate between the instances where the organ lay in the lower or upper quadrant of the scrotum, as in either position it was not exposed to trauma or subject to pressure. In no case has there been a recurrence of the hernia.

The testicle in childhood requires a free circulation for normal development. A plastic operation by which the undescended testicle is placed in the scrotum without impairment to the circulation will be followed by normal growth. Where partial resection of the spermatic vessels is necessary, atrophy may or may not ensue. Complete section of the spermatic vessels has been invariably followed by atrophy in this series of cases, the blood supply from the artery of the vas being insufficient to nourish the developing testicle. This operation should be resorted to in children only under exceptional circumstances.

# THE MECHANISM OF THE PROTECTION AFFORDED BY THE DRAINAGE OF PROSTATICS AS A PRELIMINARY TO OPERATION.\*

## A CONSIDERATION OF THE PRODUCTION OF IMMUNITY.

By HUGH CABOT, M.D., BOSTON,

*Chief of Genito-Urinary Department, Massachusetts General Hospital,*

AND

E. GRANVILLE CRABTREE, M.D.,

*Assistant Genito-Urinary Surgeon to Out-Patient Department, Massachusetts General Hospital.*

No discussion is necessary to establish the now generally accepted view that the eustom of preliminary drainage before operations for prostatic obstruction has been an important factor in reducing the mortality. Much obscurity, however, surrounds the reasons for the benefit thus produced and it is with this subject that we are here concerned. The importance of preliminary drainage is by no means equal in the various classes of cases presenting themselves for operation. It will probably be generally admitted that preliminary treatment, of which drainage is the most important constituent, is most essential in the class which comes to us with the largely over-distended bladder, sometimes stretched to the point of overflow, but in whom infection has not yet occurred. We all of us remember the dreadful mortality which accompanied the attempt to empty the bladder and remove the obstruction immediately upon coming under observation. It is notorious that these cases did badly from the start and died generally with the symptom-complex which we somewhat loosely call uremia. Perhaps the next most lethal proceeding was to operate at once upon those cases with a moderate residual of from 6 to 12 ounces and a still uninfected urine, while immediate operation was least hazardous in those cases with a moderate residual thoroughly infected and best typified by the patients who had for some time been leading the so-called catheter life. The extremes are represented by the over-distended uninfected bladder and the thoroughly infected but regularly emptied bladder enjoying a catheter life.

We shall perhaps approach the question in the most orderly fashion if we inquire what benefits are produced by the preliminary drainage which we now institute, and why these benefits accrue. The effects appear to us to be the result of two factors: 1. Relief of the so-called "back pressure," with the equalization of the kidney circulation thus resulting, and 2. Infection which, though long believed to be chiefly a

cystitis, is now generally regarded as in fact a pyelonephritis. This infection is not absolutely inevitable and there are doubtless a certain number of cases which, under the methods ordinarily employed, we believe to be small, in which the process of emptying the bladder and restoring the equilibrium of the kidney is carried through without infection. This is, however, certainly the exception, not the rule, and we are therefore chiefly concerned with the majority of cases in which infection of a more or less serious degree occurs. It has been our experience that infection is most difficult to avoid in the cases with over-distended, uninfected bladders and that the probability of infection is increased rather than diminished by the presence of the inlying catheter. The patients in whom it is most frequently possible to avoid infection are probably those with a moderate residual, still uninfected, whose urethrae are readily passable to instruments and who can therefore be managed by the process of intermittent catheterization.

Now it must be evident that the relief of back pressure upon the kidney and the infection of the kidney, which so commonly accompanies this process, both will affect the kidney function, and as kidney function is the most accurate measure of the margin of safety which these patients enjoy, we can most accurately estimate the effect of these conditions upon the patient's health by studying its effect upon his renal function. For the purpose of studying the changes in kidney function we have employed the phthalein test and, though recognizing its limitations, continue to regard it as on the whole the most useful measure of kidney function. Lumping together for the moment all the cases with residual urine treated by drainage, whether that residual be large or small, infected or uninfected, drainage produces, generally speaking, a drop in function, an intermediate period in which function remains more or less low, and a return frequently to a point somewhat below the original level but sometimes equaling, or even exceeding, it. (Figs. I, II and III and IV.) The greatest fall in function is to be expected in the cases of recently over-distended, uninfected bladders, while the least reaction is undoubtedly seen in the cases with a moderate infected residual. The very great drops occasionally seen in patients with over-distended, uninfected bladders, we believe to be due to a composite process, part of the drop being due to the relief of pressure, with consequent acute congestion of the kidney, and another perhaps equal amount due to acute pyelonephritis. Some difficulty may be experienced in assigning the proper proportion to each of these factors, but we can arrive at an approximate estimate of it by studying the cases in which only one of these factors is operative. We have been able to study a small group of over-distended, uninfected bladders which were successfully emptied and brought to excretory equilibrium without the interference of infec-

FIG. III. A man of 60. Hospital No. 199448. Diagnosis: Adenomatous prostate with uninfected residual of 14 ounces. Symptoms of pyelonephritis developed during drainage.

FIG. IV. A man of 61. Hospital No. 199551. Diagnosis: Adenomatous prostate with longstanding residual as yet uninfected. Unvaccinated. Pyelonephritis.

FIG. V. A man of 76. Admitted to the hospital Nov. 8, 1915. Private patient of Dr. Cabot. Diagnosis: Adenomatous prostate with uninfected residual of 18 ounces. Preliminary vaccination.

tion. Such cases are typified by the chart presented in Fig. V. In this case, a careful bacteriological study of the urine showed entire absence of infection from the start to finish. It will be noted that the fall was over 50% but that it never reached very low figures and rather promptly returned to something like the original level. With this we should compare the cases of pure pyelonephritis without organic obstruction, such as are seen in the early months of pregnancy or immediately after confinement. Fourteen such cases are charted in composite Fig. VI. As they entered the hospital

FIG. VI. A composite chart of 14 cases of pyelonephritis in women, all, save four, associated with pregnancy, showing excretion of phenolsulphonphthalein for two hour periods. The beginning of the curve represents the average output of phenolsulphonphthalein during disease. The end of the curve shows the average output at the time of the patients' discharge from the hospital.

with an active pyelonephritis, the low function at the first test may be taken to represent the average effect of the disease, while the rise to time of discharge represents decline of parenchymatous involvement.

With these two factors thus more or less definitely understood it is possible to see why the greatest drop should occur in the over-distended, uninfected (Figs. I and II) and why there may be little or none in the moderately distended in-

FIG. VII. A man of 66. Hospital No. 189929. Diagnosis: Adenomatous prostate with infected residual. Patient has led a catheter life.

fect (Fig. VII). In the former case, two factors, both tending to reduce kidney function, become operative at somewhere nearly the same time, the congested kidney with diminished function being further submerged by the intercurrent of a pyelonephritis. On the other hand, the patient with an already infected urinary tract is exposed only to the drop of function resulting from what one may call decompression. He is, we believe, protected from an intercurrent pyelonephritis by the immunity which he

FIG. VIII. A man of 66. Hospital No. 189929. Diagnosis: Adenomatous prostate with infected residual. Patient has led a catheter life.

has established as the result of a previous infection (Fig. VII). This, we believe, accounts for the notoriously better results of emergency operations upon patients leading a catheter life.

We are now in a position to estimate the causes operating through the kidney to produce the high mortality before the days of preliminary drainage. In the worse cases (the over-distended, uninfected) these patients were asked to survive three more or less lethal assaults all of them operating to depress kidney function and attacking them at substantially the same time, namely, decompression congestion, operation and pyelonephritis, with no previously established immunity. Drainage has had the effect of separating these three factors in point of time so that the decompression comes first, the pyelonephritis comes second and these two being survived, the operation comes third. This not only has the eminently desirable result of enabling a considerably larger number of patients to survive but the also not undesirable corollary that should the patient fail to survive the first two catastrophes, he is not added to the burden of the statistic-worshipping surgeon.

Now there is one of these three factors to which less attention has been paid than we believe it deserves, namely, the intercurrent pyelonephritis. The decompression congestion can hardly be avoided, at least to some degree, the details of the operation have commanded the attention of the most eminent, but the important kidney infection has been too much regarded as an unavoidable catastrophe. During the past year we have concerned ourselves extensively with the nature of pyelonephritis and its effect on function. The process which we here term pyelonephritis is that commonly referred to in medical literature as pyelitis. This we believe to be a misnomer, though the pathological material for the formation of an opinion is by no means plentiful, since the disease is not commonly fatal. The term pyelitis has been loosely applied to a group of cases whose chief symptoms are bladder irritation, pus in the urine, fever and varying degrees of costovertebral tenderness. This picture is practically always produced by infections with the colon bacillus, though it may possibly be produced by other organisms. From evidence already presented by one of us (E. G. C.) we believe it to be relatively clear that this is an excretory type of infection, by which we mean that the lesion occurs in the attempt by the kidney to get rid of colon bacilli circulating in the blood. Under reasonably normal conditions this feat is generally successfully performed and the kidney suffers no damage. Under conditions attended by renal congestion successful excretion often fails and kidney infection occurs. We base our opinion that this condition should be regarded as a pyelonephritis and not a pyelitis, largely upon the evidence of the marked depression of kidney function which accompanies it. We see no reason to believe that infection of the renal pelvis alone can produce any such effect on function as is here observed and there is a moderate amount of pathological evidence to show that the lesion is not simply one of the pelvis,

A case under our observation bears directly upon this question. The patient was a "prostatic" with a typical intercurrent kidney infection in which the colon bacillus was reclaimed first from the blood and later from the urine, and who died shortly after operation of hemorrhage and streptococcus septicemia. The kidneys showed a very moderate lesion of the type known as cloudy swelling, most marked in the convoluted tubules, with a still early but microscopically well marked pyelitis. In this patient a previously good renal function was depressed 20 points by the kidney infection, which, nevertheless, left but very moderate evidence of damage. To this might be added several other less fully studied cases whose clinical course entitles us to believe that they had similar lesions.

The striking fact about these cases of pyelonephritis is the amount of the effect on the kidney function as compared with the apparent lesion. In fact they are likely to be passed by the pathologist as substantially normal unless a careful study be made of the tubular area. This discrepancy may be explained by the fact that the phthalein excretion is perhaps carried on chiefly by the convoluted tubules and that a comparatively mild lesion of this area will have relatively striking functional effects. We desire also to draw attention to the fact that the permanent lesion, where such occurs, is chiefly in the renal pelvis where, in persistent cases, a chronic catarrhal pyelitis remains, giving rise to the persistent bacilluria and being the source from which recurrent invasions of the kidney, chiefly in its interstitial portions, occur.

The next important question which we are required to discuss is the mode of entrance of the bacilli into the circulation, having regard only to this particular group of cases. As tending to show that these infections are of hematogenous origin we submit the evidence already reported by one of us (E. G. C.) that blood cultures in these patients with prostatic obstruction on constant drainage are positive for the colon bacillus in a proportion of cases about equal to that occurring in typhoid fever, in which the infection is admitted to be of hematogenous origin. It is further to be noted that positive cultures are much more likely to be obtained when the blood is taken at the onset of the attack and that cultures taken at a subsequent period are more likely to be negative. In these cases it is obvious that the organism is most likely to enter the blood from some portion of the lower urinary tract and that of these structures the prostate is the most probable offender. Examination of the prostates removed from patients who have been on constant drainage shows clear evidence of an acute prostatitis and the large blood supply of this organ is such as to render absorption probable. Moreover, clinically, irritability of the prostate is not infrequently observed at the time of onset of the kidney infection, which at least suggests that it bears a causal relation. Obviously both the

bladder and the urethra may undeniably be sources of supply; the bladder, because it has been decompressed, is congested, frequently infected and not infrequently injured, while the urethra is almost invariably the site of a traumatic urethritis. Which one of these three possibilities is operative in any given case may be difficult to decide.

This briefly expresses our view of the nature of the pyelonephritis which, as we have already pointed out, is the most important avoidable incident of the preliminary drainage in cases of prostatic obstruction. We believe it to be relatively clear that the effect upon the kidney of the decompression is rarely in and of itself a factor of first class importance. The infection appears to us to be the most weighty consideration and we have come to believe that the chief benefit resulting from preliminary drainage in these cases is the immunity to pyelonephritis as a complication of the operation, which immunity is conveyed by the pyelonephritis resulting from drainage. In a word, the chief benefit of drainage to the patient is infection, not because the infection is desirable but because the immunity which therefrom results gives him a security which it has not been possible to obtain in any other way. That this immunity is of short duration seems probable from the fact that patients with a chronic pyelonephritis notably suffer from relapses of the nephritis element at longer or shorter intervals.

If now it is believed that our contention on this point is of substantial soundness the foundation has been laid for the understanding of our further proposition, namely, that it may be possible to produce immunity to pyelonephritis in these patients by a method less violent than the actual production of the disease. It has been amply demonstrated that a considerable degree of immunity to the typhoid bacillus can be produced by what is known as vaccination. The relation between the typhoid and the colon bacillus is one of reasonable kinship and it is therefore at least arguable that they may behave in a somewhat similar fashion. That the problem is far more complicated when dealing with the colon bacillus must be admitted at the outset, since the family of colon is a numerous tribe. On the other hand, it has already been shown that immunity to certain strains of the colon bacillus can be produced both in man and in animals. Our own work upon this subject has been carried on only for a period of six months, but we have been able to satisfy ourselves that in so far as agglutination can be regarded as a measure of immunity we have been able to produce it in our patients. We have worked with single strains, and with a variety of strains combined, and our clinical results to date, though too meagre to be made the basis of dogmatic assertion, appear to have been attended by some measure of success (Fig. VIII). At the outset we confined our efforts to those cases which came to us uninfected and have attempted

in them to produce a protective immunity. More recently we have extended this work to cover the cases already infected, in the attempt still further to raise their immunity to the intercurrent infections which bladder drainage is so likely to invite.

We wish to be clearly understood as presenting this only as the beginning of a piece of work which appears to us based upon sound premises and draw attention to it this time in order that the efforts of others may supplement our own endeavor, should it seem worthy of further consideration. That intercurrent pyelonephritis is for the prostatic a serious catastrophe seems to us clear; that it is in some ways a protective mechanism is at least a reasonable contention. If this protection can be established by the production of artificial immunity, a considerable advance will have been made toward eliminating an important factor in the mortality of operative procedures for the relief of prostatic obstruction.

## Clinical Department.

### PREGNANCY COMPLICATED WITH HERNIA.

By JOHN P. GARDINER, M.D., TOLEDO, OHIO.

STATISTICS show that the percentage of hernia occurring during gestation is very low. Mlle. Komarowsky<sup>1</sup> in her thesis reporting the work of Braun at the Maternity of Vienna, covering a period of 26 years and the examination of 75,659 pregnant women, found only 62 women with hernia, or 0.08%. Miller, in 9,182 pregnant women, found 35, or 0.04%. Alphi at St. Gall in 1,555 cases reports 0.6%. Harbert of Louvain found 1%.

The number of women, whether pregnant or non-pregnant, having hernia, is considerably less than the number of men. The first statistics bearing on this comparison were reported by Mounikhoff in 1836, who showed that women having hernia were about 1 to 4 as many as men. The same proportion was found by Berger<sup>2</sup> in his personal examination of 10,000 cases of hernia, who found the statistics to be: men 6,220, women 2,229, boys 1,213, girls (under 15 years) 305, making 7,443 for the masculine and 2,534 for the feminine sex, a preponderance of a little less than 75% of men over women.

Malgaigne<sup>3</sup> at the Central Bureau in Paris, in 1836, on 2,767 hernia cases, found 2,203 men and 564 women. In 1837, on 2,373 hernia cases, he found 2,884 men and 189 women, about 1 to 4 being the proportion. Jona than Maoready,<sup>4</sup> in his table of statistics for 1888 to 1890, furnished by the Truss Society,

London, reported that he found the proportion 1 to 5 for women compared to men.

The frequency of hernia in women increases from puberty to the climacteric,<sup>5</sup> while in men it remains the same. Hernias which do develop during pregnancy, particularly inguinal or femoral, frequently reduce themselves (Berger, Freund, Schauta). This procedure can be explained as a simple mechanical process. The gravid uterus, in its ascent from the small pelvis, pushes up the intestines and the uterus fills up the gap, unless the gut is adherent. However, after labor the ring is apt to become enlarged and the hernia grows worse during the puerperium, because of the relaxed condition of the supporting muscles. All authors agree as to the frequency with which women, questioned as to the beginning of their trouble, date the beginning of their hernia from pregnancy. The multiplicity of pregnancies very greatly increases the tendency to develop hernias, as was shown by Berger,<sup>7</sup> who interviewed 2,229 women of all ages having hernia and found that 1,871 had had pregnancies to term.

Umbilical hernias, unlike inguinal or femoral, hernias, occur mostly in the first year of life and become more and more rare until at 25 years of age they practically disappear. After this age they increase in frequency. Umbilical hernias are more common to women<sup>2</sup> than to men. When umbilical hernias develop during pregnancy their presence is apt to make severe complications. Of 41 cases seen by de Rycker<sup>8</sup> 10 were irreducible. The danger of strangulation increases as pregnancy progresses, de Rycker's analysis shows no case of strangulation in the first 3 months, 2 in the 4th, and one each in the 5th, 6th, 7th, 8th, and 4 in the 9th month. Pantaloni<sup>9</sup> recommends interference with all umbilical hernias during the first month as the risk of operation is less. The operative mortality of strangulated umbilical hernia is well over 50% (Coley<sup>3</sup>, Manley<sup>10</sup>).

Other hernias, more rarely met with than inguinal, femoral or umbilical, are few in infancy and adolescence and increase in frequency up to 35 and 40 years. Pre- and retro-vaginal hernias are due to pregnancy<sup>2</sup>, pre-vaginal or pudendal being the more common. These are to be reduced if possible, if not, pregnancy should be terminated<sup>7</sup>. Vagino-labial hernia<sup>2</sup> occurs in the inguinal locality. A hernia may contain an impregnated uterus<sup>10</sup>. Hernia of the white line or ventral is virtually in the same class as umbilical hernia.

Of all hernias the inguinal is the most common kind. Macready<sup>4</sup> found inguinal 50.4, femoral 31.6; Berger, inguinal 46.6, femoral 32.7. It was found that the proportion was the same for pregnant women. Komarowsky<sup>1</sup> in 35 cases, 22 inguinal, 4 femoral, 9 diverse. Either side, right or left, is about equally affected.

Inguinal and femoral hernias, occurring during pregnancy, frequently reduce themselves

mechanically as has been mentioned above. Yet, if they do persist and cause pain or distress radical measures should be resorted to. The literature on herniotomy during pregnancy is small; nearly all references are to single case instances. The largest group studied is from Engstrom's Clinic,<sup>11</sup> which comprises 18 cases upon which herniotomy was performed: umbilical 9, inguinal 8, femoral 1. They all healed per primam intentionem. Of the umbilical 2 recurred, one 4½ years after 2 normal pregnancies, and the other, during the next pregnancy.

Fischer,<sup>12</sup> in 1898, employed the Schleich method of anesthesia with success. Cushing, Bloodgood and Bodine, in 1900 used cocaine to good effect in herniotomies. With the advent of novocain combined with adrenalin the necessity of giving a pregnant woman a general anesthetic for herniotomy is done away with.

Of the three cases of hernia which the writer has had occurring during pregnancy and demanding an operation, one was inguinal and two were umbilical.

Mrs. M., aet. 26, Para II, birth of first child was 2 years ago, pregnancy normal and puerperium uneventful. She became pregnant March, 1915. July 5, while coming down stairs carrying her baby, her heel caught on the stairs. With great difficulty she recovered her balance and the effort was accompanied by a sharp stinging pain in the left groin. The pain passed away in the course of a few hours, but she noticed that whenever she was on her feet a long time, an aching pain was felt in the left groin. Early in September, an enlargement, the size of a hazel nut, was noticed and by October it had increased in size and troubled her so that she was practically incapacitated. October 15, under local anesthesia, herniotomy was performed. Recovery was uneventful. December 18, 1915, she was delivered of an 8½ lb. girl. Puerperium normal and has remained well. The cicatrix is firm.

Mrs. K., aet. 36, Para VI, had been pregnant 2 months when she began to notice a peculiar pain about the umbilicus when she lifted heavy objects. Examination revealed an umbilical hernia. In the 3d month an overlapping operation was done under local anesthesia. Recovery uneventful. Pregnancy continued normal, and she gave birth to a 6 lb. girl; puerperium was normal. The cicatrix remains firm.

Mrs. B., aet. 32, Para IV. Since the last child, has noticed a little painful swelling just at the right quadrant of the navel. It hurt her to cough or sneeze. She became pregnant October, 1911. On November 21, she underwent the overlapping operation. Recovery uneventful. Pregnancy pursued its normal course and the patient was delivered of a 9 lb. boy, July 19, 1912. Puerperium normal, no recurrence to date and she has passed through another pregnancy.

It is evident that pregnancy is one of the chief contributing factors in the production of hernia in women. From this study the writer coincides with the admonition of Berger that

every accoucheur should examine for the patency of the bernal orifices, before the recently delivered woman is discharged.

## Medical Progress.

### PROGRESS IN BIOCHEMISTRY.

BY A. EVERETT AUSTIN, M.D., BOSTON.

#### VARIATION OF THE BLOOD SUGAR CONTENT.

MANY improvements have been made in the methods of blood sugar determination, all of which tend to greater simplicity and are better adapted to the use of the clinic and the employment of smaller quantities of blood. Other investigations have also shown that the amount of sugar in the blood has much greater significance than its presence or its amount in the urine, as being much more closely associated with the sugar building and sugar destroying functions of the body.

Maase and Tachau<sup>1</sup> have performed a number of sugar estimations, employing both the polarization and reduction methods, and have shown a remarkable similarity, with the exception of one case, in the results by both methods. In this instance the amount determined by polarization power was much greater than that of reduction, apparently due to the presence of another carbohydrate in the blood whose polarization power was much greater than that of dextrose but whose reduction was much less. After the ingestion of 100 grams of fruit sugar the reduction values were much greater than the polarization and the greatest difference occurred in a case of icterus.

The estimated glucose content of the blood after the ingestion of 100 grams of levulose was repeatedly greater than the normal limit in the fasting individual.

According to Lauritzen<sup>2</sup>, the estimation of blood sugar acquires great clinical importance in the differentiation of diabetes with hyperglycaemia and diabetes without it; secondly in the determination of the prognosis of those cases where the presence of acetone and diacetic acid in the urine offers us no light concerning the increasing severity of the disease, and last

to control the results of our therapeutic efforts during which repeated determinations of the blood sugar should be made.

While previously we were compelled to depend upon the sugar-free condition of the patient's urine for the results of our dietetic management, we can now determine the foods which produce no hyperglycaemia after their ingestion, when these foods only must be taken by the patient as long as possible.

The avoidance of hyperglycaemia is not only of greatest importance in diabetes, with complications such as neuralgia, gangrene, eczemas and tuberculosis, but also in the uncomplicated mild and severe forms of the disease. It has been distinctly determined by him that hyperglycaemia, though temporary, injures the tolerance of the patient for carbohydrate when suffering from diabetes.

Dresel<sup>3</sup> has investigated the influence of extracts of glands with internal secretion on the blood sugar. The following preparations were employed by him: Extract of the anterior hypophysis, of the parathyroid, of the ovum, of the pancreas, of the intestinal mucous membrane and of the placenta. The injection of 1 cc. of these extracts causes no effect upon the amount of blood sugar; on the contrary, when injected in conjunction with 1-10 mgm. of adrenalin, which alone was able to increase the blood sugar sixteen hundredths of one per cent., the customary increase due to adrenalin was much diminished. This is particularly true of extracts of the ovum, the pancreas and the parathyroid glands. The influence of all these substances was vastly greater than that of the pituitary gland. The other extracts mentioned do not influence in any way the sugar exciting power; apparently, these substances act directly upon the central nervous system.

Brockmeyer<sup>4</sup> publishes a case of Addison's disease, in which the sugar content of the blood remained normal and showed that the severity of the disease bears no relation to the symptom of hyperglycaemia.

#### CHOLESTERIN METABOLISM.

By experiments on dogs with biliary fistulae, Fasiani<sup>5</sup> has shown that the ingestion of food after a period of fasting produces an increase in the cholesterol of the blood and of the bile. This increase is much greater after the employment of foods rich in protein and fats than after carbohydrates. An increase or diminution of the cholesterol content of the bile is always associated with a corresponding increase or diminution of cholesterol in the blood but in the reverse direction. When phloretin is injected a steadily increasing amount of cholesterol is associated with a corresponding decrease of bile cholesterol. Fasiani<sup>6</sup> on the other hand considers that there is a close relation between the cholesterol content of the blood and the bile, and that the liver is saturated with cholesterol.

Henes, Jr.,<sup>6</sup> has made numerous estimations of the amount of cholesterin in the blood in various forms of disease and has come to the following conclusions: Practically all gallstones consist for the most part of cholesterin and the increase in blood cholesterin appears to be the cause of the gallstone formation. When gallstones exist without fever, there is almost always a marked increase of cholesterin in the blood which can be employed for the purpose of differential diagnosis. This increase of cholesterin in the bile is liable to persist even after the removal of the stones, while a cholecystectomy, without removal of the gall-bladder, does not free the patient from the possibility of subsequent formation of stones.

Rothschild<sup>7</sup> has shown by experiments on rabbits that the removal of one suprarenal gland is accompanied by a moderately increased amount of cholesterin in the blood. When both suprarenals are removed a much more rapid and distinct increase of this substance in the blood is noted than by the unilateral operation. Corresponding with the double removal there is an increase of excretion of cholesterin in the bile. The distinction between the effects produced by the loss of one or both suprarenals is not great enough to regard this operation on the kidney as a producer of cholesterin and their significance, then, depends not upon their control of cholesterin metabolism, but upon their content, apparently as a storehouse.

#### PROTEIN METABOLISM.

Protein still continues to be a puzzle as to its disintegration in the digestive tract and its regeneration in the blood. That the different proteins act variously in accordance with their percentages of the various amino-acids is becoming better known, and that some of them are not efficient foodstuffs because they are so utterly unbalanced in these before-mentioned acids, which apparently form the foundation stones of the regenerated albumin molecule. Considerable work has been done by various investigators during the year.

Bornntau<sup>8</sup> has found, by feeding without protein from the vegetable foods, that the chemically proven lesser value of the grain proteins in comparison with that of animal character does not actually exist, if the grain is ground as a whole, since those portions comprising the envelope of the grain contain the missing fraction and are able, when employed with the bolted flour, to replace those amino-acids which are lacking and which make the plant protein fully equal to the animal.

Aberghalden<sup>9</sup> and his associates have shown that much less protein is needed to maintain the nitrogen equilibrium of individuals when potatoes are employed, and this same fact is true apparently of Swedish bread. During a period of ingestion of potatoes, an amount containing 4.5 grams nitrogen was sufficient to maintain the

protein equilibrium of the body. When we withdraw from this the amount of nitrogen appearing in the feces we find that upon an exclusive potato diet a nitrogen minimum of four grams is sufficient to maintain the protein equilibrium.

Zeller<sup>10</sup> has investigated the influence of fat and carbohydrate in the presence of deficient protein upon the nitrogen elimination. Seventy to ninety per cent. of the carbohydrate can be replaced by a caloric equivalent of fat without the nitrogen elimination exceeding the minimum with a pure carbohydrate regimen. For complete oxidation of the fat, the food must contain at least one part carbohydrate to four parts of fat; the urea may be diminished so that it forms only forty per cent. of the total nitrogen. The excretion of creatin and creatinin remains the same whether we employ a carbohydrate or a fat diet. The elimination of neutral sulphur is practically the same and, only when we employ a fat caloric value of ninety per cent. of the total, is increased. The amino-acid and peptid nitrogen behave exactly as the neutral sulphur. The uric acid and purin excretion sinks during the early part of the pure fat period but later with the addition of sugar exceeds the amount determined during the pure sugar period. The increased nitrogen elimination which occurs during the fat period appears to be due to the increased destruction of animal protein.

Cahn-Bronner<sup>11</sup> has shown that by feeding various split products of protein, such, for instance, as that portion of Witte's peptone which is insoluble in water, or the peptone obtained from meat and also its alcohol soluble portion, we may produce an accumulation of albumin in the liver; there are, however, certain factors which may prevent the accumulation of protein in the liver cells even when all the essentials for synthesis are present. No evidence was discovered which tended to show that it made any difference to the liver cells which of the split protein products were fed. In no instance was the parenteral introduction of protein products able to produce an accumulation of protein in the liver. These experiments show clearly that the animal organism is able, by synthesis, to produce protein from the amino-acids.

Grafe<sup>12</sup> has investigated the retention of body protein through the ingestion of ammonium salts and urea in man. In all his five individuals, the addition of ammonium chloride, ammonium citrate, urea or their combinations to a standard protein diet always produced an improvement in the nitrogen balance. Often a distinct minus balance was changed into a corresponding plus one. In all cases a large part of the nitrogen which was retained on the first day was eliminated on the following days with similar additions of nitrogen as during the period of standard diet. In four cases, however, a large amount of the nitrogen was not eliminated but apparently permanently retained. Furthermore, the nitrogen minimum could in this way be

much farther depressed. These instances with the human correspond closely with those of animals, so that they may be applied to all warm-blooded animals.

#### FAT ABSORPTION AND METABOLISM.

Nakashima<sup>13</sup> has investigated the absorption of fat in the colon and rectum. While, after the ingestion of moderate amounts of fat or cream, fat particles appear abundantly in the blood, when examined with the dark field of the microscope, thus proving its absorption, such appearances fail utterly when fat is introduced solely by rectum. When larger amounts of emulsified fat (milk or cream) are introduced into the colon, occasionally they appear, since there is a slight absorption of fat into the blood from the colon. These, however, fail utterly, when before their introduction, the ileum is ligated or cut, just above the ileo-cecal valve. Hence it appears that with rectal enemas of fat, no such absorption appears in the blood as when milk is taken by the mouth. Whether the fat may not be taken up in a dissolved form from the rectum into the blood cannot be determined by means of examination of the blood; furthermore, by physiological examination of the colon after a rectal ingestion of fat, no such appearances of fat absorption appear, as are shown in the active mucous membrane of the small intestine.

The same author has continued his investigations on the absorption of fat from the peritoneal cavity. This occurs in cold blooded animals much more promptly than in warm blooded, while casein is absorbed from the peritoneum much more rapidly than fat. Both fat and casein appear in mice within twenty minutes in the blood and can be detected for almost twenty-four hours. In frogs both substances appear in the blood within ten to fifteen minutes and remain for forty-eight hours. The absorption of suspended lecithin from the peritoneum takes place much more slowly and continues a much longer time while the fragments disappear only after a long period. The fat-absorbing power of the pleural cavity is much less than that of the peritoneum. When the peritoneum is inflamed by chemical substances, the absorption in frogs is almost normal but in mice is fully checked. This absorption of fat and casein from the peritoneum is brought about by the lymphatics without the participation directly of the blood vessels.

According to Helly<sup>14</sup>, the quantitative fat content of the liver and the visible appearances of fat are practically coincident, though there are instances in which these two factors differ. The quantitative amount of fat in the liver shows, between the minimum and maximum, no regular increase or diminution, but certain percentages are much more often favored. Hence, according to the author, the fatty degeneration of the liver is not so much a pathological process as a normal function regulated by patho-

logical conditions of other organs in which an associated activity of the central regulating power may take part.

#### INTERNAL SECRETIONS.

Since the discovery of secretin, efforts have been made to discover the relation between the external and internal secretion of the pancreas. After the introduction of secretin, the pancreas produces an amount of pancreatic juice which exceeds fourfold its ordinary amount.

Loeb and Stadler<sup>15</sup> have investigated the possibility of a stimulation of both secretions by certain substances, to determine whether they are associated with each other or entirely independent. Their conclusion is that secretin produces no influence whatever upon the sugar assimilation, hence they conclude that the external and internal secretions of the pancreas are entirely independent of each other.

Fleischmann and Salecker<sup>16</sup> have investigated the influence of glands with an internal secretion upon purin metabolism. Nucleinic acids, when fed to dogs, were almost quantitatively eliminated in the urine; when, however, pituitrin was given at the same time, the excretion of allantoin was not only lessened but also was much delayed. When, on the contrary, pituitrin was given to animals upon a purin free diet there was a slight increase of the allantoin excretion with a following diminution, although when the animal was allowed to go without any food whatever, this allantoin increase did not occur. Adrenalin, when injected in moderate doses, caused a distinct increase in the allantoin excretion without an increase in the total nitrogen eliminated. When the animals were deprived of the thyroid, the nucleinic acids which were given, were excreted in much lessened amounts. Jodothylin ingestion causes a diminution of the allantoin excretion in conjunction with a marked protein destruction. When the animals were fasting, the ingested purin bases were eliminated in distinctly less quantities, which was interpreted as a retention. Ingestion of excessive amounts of fluid always caused a marked increase in the allantoin elimination.

The elimination of creatin and creatinin in diabetes and nephritides has been carefully studied by Lampert<sup>17</sup>, who found that when a meat and bouillon free diet was given to healthy individuals, the creatinin excretion varied from 0.9 to 2.4 grams per day; creatin was generally not found at all or found in the merest traces (0.02 mgm.). In diabetes the values for creatinin were generally diminished or at least were found at the lowest point of normal values. Creatinin values remain in all cases, with few exceptions, under one gram, though there were very severe cases in which values were often found varying from 1 to 2 grams. In severe forms of diabetes, with excessive acetonaemia, creatin was always found in the urine, and in all instances far beyond the normal amount of 0.2 grams; in two

instances, amounts of 1 to 1.2 grams were found. In mild diabetes, with only traces of acetone, creatin was either absent or was found in the merest traces. In nephritis there was also a diminution of the creatinin output even when there was excellent diuresis and when the activity of the kidney was not diminished. Creatin was found in only one case of marked renal insufficiency and then only in the merest trace. Two cases of diabetes with a coincident interstitial nephritis gave especially low values for creatinin, hence the appearance of large quantities of creatin in the urine of diabetics with acidosis is the result of a pathological metabolism and the diminution of creatinin in the urine of nephritics is the result of renal insufficiency.

#### NATURE OF IODINE IN THE THYROID.

For many years efforts have been made to determine the character of the iodine in the thyroid as well as the laws governing its metabolism. These researches have been continued during the past year with much enthusiasm by various investigators.

Among these, Blum and Grützner<sup>18</sup> found that by far the greater part of the iodine in the thyroid is firmly combined with protein. In addition, a very small fraction may be found which is soluble in acetone and is probably iodide of potash. This amount of iodide of potash was found to be independent of any ingestion of that substance and also present in such animals as had received only milk, rice or meat as food. No constancy of the thyroid iodine content was found, at least in dogs; on the contrary, when iodide of potash was ingested, there was a manifest increase in the combined iodine of the gland. This increase, then, must be due to a physiological action by which inorganic iodine is converted to organic or combined. This process is specific in the thyroid, as it occurs in no other organ of the body. When one thyroid was removed and potassium iodide was given the animal, the amount of iodine in the remaining gland was distinctly increased; when no iodine was given, the remaining gland maintained its iodine content without change, but if it were previously enlarged, the iodine content was found later increased. These findings are not to be interpreted as indicating an internal secretion of iodo-proteins on the part of the gland but intraglandular elimination of the iodine absorbed, much as the antidotal action of the liver with mercury.

The same authors distinguished very sharply between iodine metabolism and iodine secretion on the part of the thyroid.

A systematic elimination of iodine or one which continues for any length of time is never found in the organisms of warm-blooded animals except in the thyroid. The lymph glands associated with the thyroid were always found free of iodine. Other organs of normal animals which were examined contained in a few in-

stances, but irregularly, inorganic iodine, probably derived from the food but never the combined metal. After persistent ingestion of potassium iodide, the presence of iodo-proteins was never detected apart from the thyroid. Hence the combination of iodine with protein must be a specific activity of the thyroid alone.

## Reports of Societies.

### BOSTON SURGICAL SOCIETY.

(Incorporated.)

#### ELEVENTH MEETING.

A stated meeting of the Society was held on Monday, March 6, 1916, at the Tavern Club, at 8.15 P.M.

Dr. W. P. GRAVES read a paper on the

#### PRACTICAL ASPECTS OF THE INTERNAL SECRETION OF THE OVARIES.\*

Discussion of Dr. Graves' paper followed:

Dr. H. T. HUTCHINS stated that ovarian therapy had not been reduced to any scientific basis of standardization. We can use tablets of ovarian sub-

\* Dr. Graves' paper was published in the August number of the *New York State Journal of Medicine*.

DR. C. L. SCUDDER reported for the committee on end-results of the treatment of infected joints, that a sub-committee had been appointed consisting of Drs. Irving, Walker, Ehrenfried, Miller and Harmer, and that the collection of data was progressing.

The meeting then adjourned.

(Signed)

ROBERT B. GREENOUGH,

Secretary.

## FALL MEETING OF THE NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION.

HELD AT THE HARVARD CLUB, BOSTON, NOV. 30, 1915.

PRESIDENT, A. L. CHUTE, M. D., BOSTON.

SECRETARY, R. F. O'NEIL, M. D., BOSTON.

### DEMONSTRATION OF CASES, INSTRUMENTS AND SPECIMENS.

#### A DEVICE FOR HOLDING THE HAGNER BAG IN POSITION.

DR. W. W. TOWNSEND: I have a Vermont product which I hesitate to present to this critical audience, but it has been one of great value to me in the retention of the Hagner bag. It is simply a wire frame, the bag being introduced in the usual manner, this clothes-pin wire arrangement is put on to hold the air in the bag. The frame is then slipped over the penis. A piece of gauze is applied at the root of the penis so that the counter pressure against the pubes will not hurt the patient. After the bag is in place the tubular portion is pulled forward and hooked into the hook at the end of the wire, which maintains the traction on the bag very satisfactorily.

#### END-RESULT OF A CASE OF TOTAL CYSTECTOMY.

DR. ARTHUR H. CROSBIE: At a meeting last winter I reported a case of carcinoma of the bladder in which I did a total cystectomy, removing bladder, prostate and vesicles. I have now to report that two months ago the man died of a recurrence. I have brought up the specimen to show again tonight as some of you may be interested in looking at it if you did not see it at the last meeting.

#### SPECIMEN OF A VERY LARGE PROSTATE.

I would like to show a prostate which Dr. Chute took out. This gland was removed from a man 76 years of age who had led a catheter life for four years. The prostate is remarkable purely because it is so large, the total weight being 320 grams.

#### A CASE OF EMERGENCY PROSTATECTOMY FOR HEMORRHOGE.

DR. R. F. O'NEIL, BOSTON: It has seemed to me that the following case presents certain points of interest which make it worth while reporting. The patient was admitted to the G.-U. Service at the Massachusetts General Hospital for severe hematuria. History of urgency, frequency, and inability to hold his urine, for three years. Rectal examination showed a large, smooth elastic prostate. Reflexes normal.

A catheter soon became plugged and the bleeding increased. I then decided to open the bladder suprapubically, check the bleeding, and do a two-

stage operation. On opening the bladder under local anesthesia, the knife plunged directly into a solid tumor which proved to be an enormous median lobe practically filling the bladder. Drainage being obviously out of the question for mechanical reasons, gas-oxygen anesthesia was given, and the median lobe, together with two good-sized lateral lobes, was enucleated, in spite of the fact that I knew nothing of the man's renal condition. There was nothing else to be done. He made a good recovery after a rather stormy convalescence, which included a periurethral abscess, epididymitis, and bronchopneumonia.

#### A CASE OF DIVERTICULUM OF THE BLADDER, AND A CASE OF DILATATION OF THE URETERS SIMULATING BILATERAL DIVERTICULA.

DR. R. F. O'NEIL, BOSTON: These cases are reported together as they were in the ward at the same time and were supposed to have similar lesions. Case I seems to emphasize the error in diagnosis in Case II.

In Case I the cystoscopic findings were borne out at operation. In Case II operation showed that what we had taken for diverticula were the much dilated ureters; the case being one of the rare so-called cases of insufficiency at the uretero-vesical junction. (The condition has been recently described by Kretschmer, Urological Transactions, Vol. ix.) Had we injected more silver solution into the bladder at the time the x-ray was taken, the true condition would doubtless have been discovered.

Case I. The patient, a man of 40, was first seen in the G.-U. Out-Patient Department of the Massachusetts General Hospital. Presenting symptom, frequency of micturition. He had a turbid urine and a residual, without any obstruction. Cystoscopy showed the orifice of a diverticulum on the right not involving the ureter, and more or less trabeculation of the bladder. He was sent into the hospital for operation. The diverticulum was successfully excised, and the patient made a good recovery, although the urine remained cloudy for a long time.

Case II. G.-U. Service, Massachusetts General Hospital, a young man of 20. Fourteen months ago urinary frequency and pain which had recently stopped. Urine cloudy.

Cystoscopy: On one side, in the general location of where the ureter should be, was a round hole resembling the orifice of a diverticulum, which we assumed it to be, with the ureter emptying into it. An x-ray catheter was passed into this and the radiograph showed the catheter curled in a circle upon itself as if it were coiled up in a diverticulum. The ureter on the other side appeared somewhat dilated, but not to the same extent. A radiograph of the bladder filled with argentine solution showed a bulge on either side. On the evidence of this and the previous x-ray, a diagnosis of bilateral diverticula was made. The renal function was, time of appearance 11 min.; 20% in first hour, 15% in second.

At operation, on opening the bladder, the two openings seen through the cystoscope in the general location of the ureters, were found. Catheters passed into these failed to go any distance. On stripping back the peritoneum and exploring the base of the bladder, these were found to be the openings of the ureters which were enormously dilated all the way to the pelvis of the kidney. Although these orifices appeared somewhat abnormal,

their appearance was not such as to cause one to suspect the presence of the tremendous dilatation of the ureters which was found.

DR. GEORGE G. SMITH gave an account of his experiences as Surgeon to Mrs. Depew's Hospital at Compeigne, France, illustrated by lantern slides.

DR. C. G. MIXTER of Boston read a paper entitled,

UNDESCENDED TESTICLE IN CHILDREN.\*

DISCUSSION OF DR. MIXTER'S PAPER.

DR. J. D. BARNEY, BOSTON: There is little that I can add from a clinical standpoint to this good paper, but I thought it would be of interest to look up what material we had on this subject at the Massachusetts General Hospital.

In the card catalogue I found there were 198 cases reported in all ages, and that these occurred singly in 185 and doubly in 13. That seems to bear out the testimony of others that bilateral undescended testicles are quite rare. One hundred and thirty-four of these cases, or 66%, were accompanied by hernia of one or both sides. I understood Dr. Mixter to lay more stress upon the hernia than these records would warrant.

In looking over the literature on the subject I find that in 59,000 or 60,000 cases of hernia in children in the hospitals of New York there were only 137 cases of ectopic testicle.

A good deal of stress has been laid upon the occurrence of sarcoma. In our series there were only three cases, a trifle over one per cent. We found hydrocele in only eight cases.

I do not think it is at all strange that we should get hernia or hydrocele because there is a direct communication between the abdominal cavity and the scrotal cavity. I think it is a little more striking that there are so many who do not have hernia.

In regard to sarcoma I find interesting figures. Out of 182,729 admissions to various hospitals in England and in this country, there were 117 cases of sarcoma of the testicle. Only twelve of these were in the ectopic stage, and only three were of the intra-abdominal type, the others being inguinal in one position or the other. And then strangely enough Dr. Bulky of New York reported two years ago two cases of sarcoma of the ectopic testicle, and found that there were only 59 others reported in the world's literature. This struck me as being quite startling. He came to the conclusion that you might expect sarcoma in one out of every 75 ectopic testicles. My impression was, and I think it is generally supposed, that the ectopic testicle is peculiarly liable to sarcomatous degeneration, but apparently it is far from common.

I would like to ask Dr. Mixter what the indications are for operation on a case of undescended testicle in children. I would like also to congratulate him on his paper.

DR. G. G. SMITH, BOSTON: I think that it should be borne in mind that atrophy occurs in the spermatogenic system, and yet not in the interstitial cells of Leydig which furnish an internal secretion. I believe it has been shown by experimental work that although the spermatogenic function may have entirely disappeared, the cells furnishing the internal secretion are apparently spared.

DR. HUGH CABOT, BOSTON: The evidence submitted by Dr. Mixter, that free division of the veins of the cord in bringing down the testicle in operations for failure of descent results in atrophy of the testicle, is a contribution of first-class importance.

This principle of free division of veins was, I think, first advocated in a thorough-going way by Beyer and was perhaps the most important part of his operation. It has been satisfactorily shown by clinical experience that such a free division can be done without causing necrosis and for this reason it has been assumed that it was free from serious objection. Dr. Mixter's contribution goes far to show that though necrosis does not occur, atrophy does, and should this evidence be confirmed by a larger group of cases, division of the veins as a part of this operation must be finally abandoned.

DR. W. T. COUNCILMAN, BOSTON: In connection with this paper of Dr. Mixter's, I happened to read the other day in the Memoirs of Nathan Smith, which were published by his son, Nathan R. Smith, in Baltimore, the report of one of his operations for hernia in 1823. In this case the hernial mass was very large and solid, and in the course of operation he was much surprised to find in it only a small knuckle of intestine. Outside of this there was a large tumor mass which was composed of a testicle, a hydrocele cyst, with an enormous thickening of the tunica vaginalis. The article contains a picture of the condition.

DR. J. W. KEEFE, PROVIDENCE: I should like to mention another condition and that is the twisting of the testicle sufficient to destroy the blood supply, producing a necrosis of the undescended testicle.

I know of an instance of a child about one and a half years old which had that result. The physician was called, and thought he had an inguinal gland, and he applied ice, and later the swelling persisted and I found it necessary to remove the testicle. Another interesting point about this case was that the father of this boy, when he was a man about 26 years of age, had the same condition, when the late Dr. Maurice Richardson saw the case with me; and he made a diagnosis previous to the operation, that we should probably find the testicle so twisted that the blood supply was interfered with. I have felt that many of these cases are atrophied testicles.

In regard to the fact that sarcoma results, the books have told us that it frequently happens. I recall the case of a doctor some 75 years of age who had enlarged prostate for which I operated, and he had two undescended testicles in the inguinal canal. It may be as Dr. Barney has shown, that we do not find sarcoma of the testicle so frequently as the books have taught us in the past.

DR. G. G. SMITH, BOSTON: I should like to ask Dr. Mixter if he remembers what age the children were who had the atrophied testicles. There were two of them, he said, that were atrophied at the time of operation.

DR. J. D. BARNEY, BOSTON: On the other hand, I recall the fact that in a paper published by McClannan in 1913, it was shown that the spermatogenic function is not done away with as frequently as we supposed. In many cases it was still persistent, as shown by the microscopic sections of the testicles, and in the cases in which it was sup-

\* See JOURNAL, p. 631.

posed that there were no spermatogenic cells, there were plenty of them.

**DISCUSSION CLOSED BY DR. MYTER:** The one point which I wanted to make was that I consider this, the Bevan operation, of complete section of the spermatic veins in children, a dangerous procedure as far as the developmental result goes. I think that if this small series is of any value the fact that every case in which complete section was done was followed by atrophy is pretty striking, to say the least.

On the other hand, in every case reported in which the vessels were left absolutely intact, no atrophy resulted.

I cannot of course speak in any way about the spermatogenic function in these cases.

In regard to the indication for operation on undescended testicles in children, one point is the fact that of this relatively small series two cases showed marked atrophy at the time of operation. Those two cases were out of 30 cases operated on.

I cannot tell you the exact ages of those two children, but my remembrance is about six and nine years respectively. The indication for operation in younger children is, as I said,—in the first place, where there is evidence of a beginning atrophy, and in the second place, where the hernia gives rise to trouble and not on account of the testicle.

I see no reason why the testicle should not be operated on after three years or some age in that vicinity, because I think as good a result can be expected as there can be in older children or adults, and there is less danger of atrophy occurring spontaneously.

**DR. HUGH CABOT** of Boston read a paper entitled:

THE MECHANISM OF THE PROTECTION AFFORDED BY THE DRAINAGE OF PROSTATICS AS A PRELIMINARY TO OPERATION.

A Consideration of the Production of Immunity.\*

**DISCUSSION OF DR. CABOT'S PAPER.**

**DR. W. T. COUNCILMAN, BOSTON:** I have been much interested in Doctor Cabot's paper. A great part of it is outside of my province, but the main point of the paper, as I understand it, is the production of immunity before operation, and this seems to me very interesting. It must make an enormous difference whether in consequence of an operation an infection is produced in an individual previously free from infection and who has no immunity, or whether the infection is produced in an individual who has already acquired a very high degree of immunity. The degree of immunity which these patients sometimes attain seems to me very remarkable. I some time ago performed an autopsy on an old gentleman over seventy, who for over twenty-five years had been accustomed to use a catheter eight times daily. The catheter was carried in his pocket, and he was accustomed to lubricate it with saliva in order to facilitate passage. In the course of his life he had had numerous infections in the urinary tract, in the epididymis and prostate, and most of these parts had become sealed off from the urinary tract by chronic inflammation. There was a constant cystitis of not very high degree. For some years before death there had been no infections, and the general condition of health was good.

At the autopsy I expected to find in the kidneys evidences of old abscesses, a high degree of pyelonephritis, and general atrophy of the kidney. I found nothing of the sort. The kidneys were extremely good for an individual of that age, and there was only a slight degree of thickening of the pelvis.

What Doctor Cabot has said is also in agreement with what many of us are thinking in these days; the very great care to avoid infection, in food, in milk, and by our manner of life, may not be wholly to the good. We are possibly doing ourselves harm by not developing immunity to infection, which can take place only by our acquiring infection; it can easily happen that at some time a malignant strain of some organism may be encountered which in the absence of all immunity may be attended with serious results. Possibly the milk epidemics which have been so severe a few years back, may have been associated with this rather artificial absence of immunity. It seems, however, a very novel thing that the surgeon, whose efforts are directed generally to the avoidance of infection, should deliberately produce it. A second point in Doctor Cabot's paper is in regard to the mode of infection. There is nothing more difficult in pathology than to determine in the first place the point of entry of organisms into the tissues, and secondly the mode of extension of the infection from the primary focus. There are so many possibilities in regard to this. If we take for example the progress of such a disease as tuberculosis of the lung: every channel of infection is called into play, such as blood vessels, lymphatics, the surfaces, etc. In all infections the extension by means of surface plays an important part. The extension of infection along the urinary surfaces is very important, and affords an interesting example of surface extension. The pathologists recognize distinctly two modes of infection in the kidney: the hematogenous or the descending and the urogenous or the ascending. I have thought that Doctor Cabot rather doubts the latter, especially from some rather sarcastic utterances of his with regard to the hypothetical natatory powers of the tubercle bacillus. Infection can very easily take place along a surface in a direction contrary to the flow over such a surface. One of the examples of this is the extension of infection from the mouth to the parotid gland. There the infection extends through a narrow channel which is well protected by an epithelial surface and against a pretty constant current. It is sometimes very difficult from the anatomical lesions to interpret the mode of infection. In the kidney both the hematogenous and urogenous are frequently combined. In the pyæmic diseases, such as scarlet fever, diphtheria, ulcerative endocarditis, we frequently find foci of suppuration in the kidney which are definitely hematogenous in origin. They are usually most prominent in the cortex. There are also undoubted cases in which there is infection of the kidney which follows upon infection of the pelvis of the kidney. There are certain anatomical distinctions between the two. In the urogenous infection, the lesions are chiefly in the pyramid, and we find in this and extending from it, long white lines of necrosis with central masses of organisms. It is perfectly possible, however, to have an infection begin in the cortex of the kidney and extend downward along the urinary tubules, in which case the most marked lesions may be in the pyramid of the kidney. Even in the hematogenous infections, the lesions may be more marked in the

\* See JOURNAL, 1916: 633.

pyramid of the kidney, and may closely simulate a urogenous infection, because the organisms may pass through the capillary circulation and find lodgement in the long veins of the pyramid. If a culture of *staphylococcus aureus* is injected into the ear vein of a rabbit there are always lesions produced in the kidney which are usually more marked in the pyramid than in the cortex. In tuberculosis, undoubtedly both modes of infection take place and they are difficult to distinguish. In general military tuberculosis, the tubercle formation is most pronounced in the cortex, but even here the lesions may be in the pyramid and from the cortical lesions there may be a further descending infection. The pelvis of the kidney, moreover, in tuberculosis, can become infected, and from this point the infection can again advance toward the kidney. On the other hand, we undoubtedly find cases of ascending urinary tuberculosis, in which the lesions below are undoubtedly of an older date than the lesions in the kidney. There is no difficulty, it seems to me, in regard to the passage of organisms from the bladder upwards. We must not think of the flow of urine in the ureters as a rushing torrent, carrying all before it, against which the weak bacillus has to struggle, but conditions easily arise in which there is no current at all, and organisms in one part of the common fluid in the bladder and ureter can be diffused through the fluid by means of the currents which are always present. Such currents may be produced by the intermittent pressure coming from the intestines or in various ways. It is also perfectly possible for the tubercle bacilli to advance along the surface from point to point, finding lodgement on the surface and growing there. In regard to the excretion of organisms by the kidney, I have always had a great deal of doubt as to whether this does take place without lesions. Lesions of the kidney are extraordinarily common in all of the infectious diseases, and from such lesions the organisms can enter into the urine where they will multiply and a condition of bacilluria which may be long in duration will be produced. This seems to me to be the case in typhoid, for instance. The experimental evidence which we seem to have, in which very large quantities of organisms are injected into the blood and later make their appearance in the urine, does not seem to me to be worth much unless accompanied by the most painstaking examination of all parts of the kidney. I always like to hear these clinical papers, especially when presented so ably as the papers were this evening, and I always regret the lack of clinical knowledge on my part, which prevents an adequate discussion.

DR. A. L. CHUTE, BOSTON: This general subject is something that has been of the greatest interest to me and upon which I hold pretty definite opinions that I have set forth in one or two papers written within the past few years. To me Dr. Cabot's theoretical views as to the source of these infections are extremely interesting but not wholly convincing. His suggestion regarding vaccination as a possible method of preventing or minimizing these infections is very attractive, but its value is not as yet proved; and I wish to warn against a too enthusiastic following of this method until we have more definite knowledge regarding it. It seems to me that there are several reasons to make us slow in adopting it until we have further evidences regarding its value.

From the theoretical point of view, I am in doubt

about one's ability to immunize these men with colon vaccine. If this were possible, more of the very constipated patients ought to develop a pretty good natural immunity, and yet we rarely see men who seem to show any signs of this.

Another objection to the plan is that it takes time to immunize patients by vaccination, and often one can ill afford to spare this time in the prostatitis with bladders overdistended with clear urine. My greatest objection, however, is that in following this method we should be substituting a cumbersome way, even if it were demonstrated to be an efficient way, for the simpler method of opening the over-distended bladder under novocaine and draining by means of a large suprapubic tube. This way, it is true, does not prevent infection of the bladder but it prevents, to a very large degree, the harm which comes from this infection; namely, the serious infection of the kidneys. Combined with this combating of the infection, it has the advantage of relieving the kidneys of the mechanical factor of back pressure in a manner that is more complete than is possible with any other way of drainage. The fear of serious collapse from opening an over-distended bladder or the danger of serious hemorrhage are under these conditions, so far as my experience is concerned, mythical, when this operation is carried out under local anesthesia.

I am sure we all appreciate Dr. Councilman's kindness in coming here this evening and giving us so clear an exposition of the pathology of the condition under discussion.

DR. E. G. CRABTREE, BOSTON: We recognize that in the paper which Dr. Cabot has just read there is a radical departure from the well-beaten textbook path of consideration of pyelitis. We regret that the paper is of necessity based upon incomplete evidence and a rather small number of cases, yet certain definite facts are indicated which have some bearing on the general subject. It is to be hoped that our search for truth may not seem to lead to our discomfiture as in the case of the man who, searching for stars by day, fell into a well.

Certain evidence has been produced in experimental laboratories which indicates that the kidney has a definite excretory action for bacteria. I have myself endeavored to demonstrate the point and, following the suggestion of Carl Ten Broeck, injected attenuated cultures of para-typhoid bacillus into the ear veins of a rabbit and recovered them from the urine in large numbers 18 hours later. A drop of urine from the bladder, which previous examinations had shown to be sterile, gave innumerable colonies on the culture media.

In regard to the existence of a blood infection during pyelitis, to which Dr. Cabot referred in his paper, certain evidence has been produced in my clinic. I have taken blood cultures on 32 cases, including 9 cases of prostatitis with infected urine at the time of entrance into the hospital. These cases all showed a clinical picture of pyelitis at some time during their stay in the hospital. I have obtained positive cultures of the colon bacillus in 13 cases. Of the 9 prostatitis examined, positive blood cultures were obtained in 7.

The demonstration of the results of vaccination is a difficult problem and must rest on clinical as well as laboratory findings. So far as agglutination is a factor of protection, the use of vaccine has apparently accomplished some good. There is some evidence that infection itself produces immu-

nity. It has been found in 3 cases in which there had been more than one attack of pyelonephritis and in which the colon bacillus had been recovered from the blood, there was a distinct increase in the agglutinating power of the serum. Likewise I was interested to find in the case of a man who had recently had 4 attacks of epididymitis due to the colon bacillus, his agglutinating power was much increased although he had not been vaccinated.

In cases in which colon bacilli have been recovered from the blood, there are two possibilities to be considered: one, that the infection enters the circulation from some point outside the genitourinary tract; and the other, that the blood is infected from an infected kidney. In our one case where careful bacteriological and cultural evidence has been produced, we obtained a positive culture from the blood previous to the appearance of the bacilli in the urine. Bearing upon this subject, last month's issue of *Jahrbuch für Kinderheilkunde* contained a review of some work by Kowitz, who had traced the order of appearance of bacteria, pus and albumin in 5 children in whom pyelonephritis developed in the course of an infectious diarrhoea. He found the order of appearance to be 1. albumin, 2. bacilli, and 3. pus. In regard to the frequency of blood infection in infectious diarrhoea, the same author quotes Baer, who found in 117 cases of infectious diarrhoea positive blood cultures of colon bacillus in 65.

I have recently read in the literature, but do not know what significance to attach to the observation, that in leprosy and tuberculous patients the use of salvarsan is followed by showers of the respective bacteria in the urine and often attended by spread of the disease.

In obtaining blood cultures of the colon bacillus, my experience has shown that it is useless to take the cultures at any considerable time after the onset of symptoms. I took blood cultures later, for a time, with almost uniformly negative results. Apparently the only time at which positive results may be obtained is at the very beginning of symptoms of pyelonephritis. Likewise in cultivating the colon bacillus from the blood, inasmuch as the immunizing power of this organism is less than that of the typhoid bacillus, the amount of blood which can be taken without danger of interference with growth is considerably greater. I take 10 cc. for each flask of culture media.

DISCUSSION CLOSED BY DR. CABOT, BOSTON: The discussion between those who have regarded renal infections as commonly haematogenous in origin and those who have regarded them as generally urogenous has long been violent and has acquired the dignity of antiquity.

It was not our intention to stir this hornet's nest at this time, though we shall have much to say on it later. However, as the question has come up, it is proper to indicate our views at this time.

The advocates of urogenous or ascending infection as the common source have always had an attractive doctrine and one peculiarly seductive to the unwary. Its weakness has lain in the fact that it has postulated certain conditions which are difficult of demonstration and which, in our opinion, do not in fact exist. In many of these cases of acute colon bacillus pyelonephritis the infection occurs in persons having no previous lesion of the lower urinary tract and in whom there is no condition likely to produce one. This is particularly

true of the cases occurring in children and in women, more especially in relation to pregnancy, and yet in these cases the lesion is precisely similar and the disease runs the same course as in those having some pre-existing lesion of the lower urinary tract. The advocates of ascending infection have had to disregard entirely the notorious fact proved both clinically and by animal experimentation, that the bladder is peculiarly resistant to infection introduced through the urethra and that in the absence of retention, infection of that organ can be produced only with the greatest difficulty. Under these conditions, to assume that the colon bacillus transverse the urethra, infects the bladder, ascends the ureter and involves the kidney requires a feat of imagination which is quite beyond us.

In favor of the excretory origin of these infections is the also well known fact that colon bacilli circulate in the blood and are excreted by the kidney under a great variety of conditions, in many of which their presence has been entirely overlooked. The best recognized cases are those of the first cousin of the colon bacillus, the typhoid bacillus, in which the excretion of the bacteria by the kidney has long been recognized. We believe that evidence is at hand to show that the colon bacillus behaves in a precisely similar fashion and that his presence in the kidney is extremely common. Thus the believers in the excretory theory can at least deliver the colon bacillus at the kidney without straining their imagination and from this point explanation of the lesions becomes a simple matter. This makes it incumbent upon the advocates of the theory of ascension to show a previous lesion of the lower urinary tract, most commonly of the obstructive type and clearly antedating the infection of the kidney. Where this can be shown, ascending infection is about as likely, though not more likely, than excretory infection, and in these cases the two types are theoretically on a par. We believe that the ascending theory of these infections has seen its best days and that in the future it will be on the defensive rather than on the offensive and will play a losing game. That it will ultimately be proved to account for a certain proportion of cases is probable, but these will, we think, be the minority.

In regard to Dr. Chute's views, I hope, with him, that the theories we have put forward this evening of what it may be possible to do, will not stampede anyone. I confess I have little fear of stampeding this gathering and yet if it should succeed in drawing some surgeons away from the method of two-stage prostatectomy, to which Dr. Chute is apparently wedded, I cannot believe that much damage will be done. The two-stage operation seems to me unsatisfactory and I am not prepared to admit that it avoids the infection of which we have been talking this evening any more surely than do other methods of drainage. Furthermore, in my hands it has not been certain to avoid a considerable mortality. The two-staged method, as proposed by Dr. Pileher at our meeting last winter, seems to me clearly preferable to any other method that I have seen, but even this I am by no means clear that we are not unnecessarily wasting the patient's time and requiring confinement to bed for a period which with these patients is certainly serious. The two-stage operation is unsatisfactory, and if by a process of previous immunization we can avoid it, I think we shall have accomplished an important result.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, NOVEMBER 2, 1916

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

An editor will be on the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## HUMAN TYPES IN THE ADOLESCENT PERIOD.

NUMEROUS papers have recently been presented, several of them in this JOURNAL, bearing upon what might be called the theoretical side of the question of type in the human, as expressed by the words *carnivorous* and *herbivorous*, or their synonyms. To the theory of type it has been objected that, even should it prove true in its entirety, it would yet remain without practical value. This objection seems by way of being refuted; thus Bryant has mentioned two independent practical investigations in progress. One, by Dr. Hodskins of Monson, is a study of type in relation to the single disease group of epileptics. The other concerns itself with manifestations of type in school children. Notes upon the second of these studies are now available, for Dr. Lewis of Worcester has published his results of an examination of 547 unselected school children in his city under the

title "Adolescent Physical Types: A Preliminary Study."

Having extensively considered the literature, Dr. Lewis proceeds to review his material, dividing it into three classes or types of body form, under the headings *carnivorous*, *herbivorous*, and *neutral* or *ideal normal*. The most striking fact elicited is that out of a group of over 500 boys of school age, less than 50, or 10%, could be placed in that favored normal group which since before the days of Phidias and the Golden Age of Greece has been held representative of the ideal in the physical development of man. The word "favored" is used advisedly, since his study has convinced Dr. Lewis that the fortunate few in this select ideal normal group possess within their perfectly formed bodies not only a maximum of resistance to disease, but a maximum prospect of a superior mentality. Thus is additional scientific evidence—were further needed—available in support of the truth of the ancient empiric proverb of the sound mind in the sound body. Scarcely less striking than the small incidence of the ideal group, is the fact that this 10% appears to represent, so to speak, a total effort of nature in the matter of perfection, since the 10% runs practically constant, regardless of race or social status.

Anatomies are written and illustrated, and medicine is taught according to this investigation, then, upon a basis of but 10% of humanity. As a result, when the young graduate in medicine is confronted by a patient, he may have the satisfying thought that there are about nine chances to one that the patient he is considering is not built according to the plan which he has so diligently studied.

What may we learn of these other nine people in ten? Dr. Lewis finds that his boys are not grouped evenly upon either side of the normal, but that they fall in the proportion of two to one on the *carnivorous* side of normal, with this tendency even more strongly shown among those of American birth.

If for every normal there are three *herbivores* and six *carnivores*, it becomes of some interest to know what physical and mental tendencies may be found in these predominating groups, with their 100% excess of *carnivores*. Dr. Lewis gives direct support to previous observations on the types, as follows: "My statistics indicate, first, that *good* posture, muscular function, nutrition and teeth are correlated with the *neutral* or *omnivorous* type, second, that *fairly*

good posture, muscular function, nutrition and teeth are correlated with the herbivorous type; third, that incorrect posture, physical defects, prominent lower abdomen (visceroptosis), insufficient muscular function, poor nutrition, defective teeth and rickets are correlated with the carnivorous type.

In general, the boys of the carnivorous group are weak, poorly nourished, lacking bone and muscular resistance in addition to having poor posture. Often the history shows diseases and other defects which greatly reduce the vigor and health of the boy, decrease his resistance to abnormal and long-continued strain, and predispose him to spinal curvature and the like. The history of diseases, as recorded on the cards, shows that headache, measles, scarlet fever, pneumonia, pleurisy, tonsillitis, and convulsions occurred about three times as frequently in the carnivora as in the herbivora. Invariably, the boys with poor marks in studies were poor in physical training.

In all types there seemed to be a direct correlation between physical and mental activities. The best marks for study and training were found in the neutral group. There were only three fair grades in study, and all grades good or excellent in physical training. Seventy per cent. of the herbivorous type have good or better grades in physical training and about 30% good in studies. Fifty per cent. of the carnivorous type have good or better in physical training, and about 30% good in studies. There were no failures in studies in the neutral group, two in the herbivorous group, and eight in the carnivorous group."

From these figures it appears that two-thirds of these 500 boys belong in a type proved to be about three times as subject to disease as the next most frequent group of boys. Further, it appears that this most numerous group is the worst developed physically. Yet, if complete failures are eliminated, it appears, that in spite of the physical handicaps which predispose to poor mentality, the average grade in studies is no worse for the poorly nourished carnivore than it is for the more perfectly developed herbivore. One inference is, perhaps, that were the carnivore given an equal chance physically, he might excel the herbivore mentally.

Whatever inferences may be drawn, however, such findings as these of Dr. Lewis are worthy of serious thought by all interested in matters

educational, and in the newer aspects of preventive medicine, and it is to be hoped that this is, indeed, but the forerunner of many similarly interesting and valuable practical studies in human development.

## HEMATOGENOUS INFECTIONS.

REPORTS of certain laboratory investigations, not generally accepted but worthy of much attention (Rosenow), indicate a possible great extension of the field now occupied by the streptococcus in pathology. Diseases now generally believed to be due to a blood-carried infection are mainly endocarditis and arthritis. Others quite probably always in this category are pyelitis, chorea (of the non-imitative type) and purpura. If we are to include also gastric ulcer, appendicitis, neuritis, myositis and other such disease conditions, we shall have a group as distinct and as large as that of syphilis and greater than that of tuberculosis.

Excluding the colon group represented by pyelitis and perhaps some forms of arthritis, the principal part of these diseases represents, we believe, a streptococcus infection which gets into the blood stream almost certainly from the mouth, throat, eyes, ears, nose, or a wound of the skin. Of these possible sources, the teeth or tonsils are nearly always the most likely. Bacteriologists (Ernst) believe that such a streptococcus is not present in the gastro-intestinal tract.

Removal of these sources and the administration of some antagonistic drugs after the disease is once started is not satisfactory treatment. Once lodged in the tissues of the body, the organism or its effects are very persistent.

What is to be emphasized is that practically all of this large group of diseases can well be considered to originate from primary disease of teeth or tonsils; that once started, consistently successful treatment cannot be said to have been achieved; and that the majority of physicians are still so careless as not to accomplish the prevention of these infections. It remains to be seen whether a pediatricist cannot definitely promise freedom from all diseases of this type so long as a patient obeys his directions. Prevention, we think, should start in infancy, and begins with the maintenance of good health. Given a healthy infant at six months, it is ques-

tionable whether we utilize his good digestion to his best advantage by not choosing his food for a more distant future than we can for those in poor health. Do we not too often sit back and watch him gain weight satisfactorily on a simple milk diet?

Durand of Seattle, Owre of Minnesota, Wallace of London, and others, publish favorable results of this choice of food on the teeth. Ordinarily, suppuration about teeth is easily seen if looked for. Cases in which a pus pocket can be detected only by x-rays are so common, however, that this method may be much too infrequently used. Just when this examination may be safely omitted has not yet been determined, so it may be more safe to use it in every case where a tooth is badly carious, even if the gums seem healthy. In children with poor teeth, a routine examination by the x-ray ought to be made every six months. Most dentists cannot guarantee complete safety in cases of suppuration by treatment without extraction. We think that safety from these diseases is more valuable than the retention of inferior teeth which, it is conceivable, may transmit disease to other healthy teeth in contact.

Radical treatment of all even faintly suspicious tonsils may seem impracticable, but it must be remembered that in childhood the painful convalescence, which is the worst of the operation for adults, is very much shortened—in fact, it is the usual thing for such a patient to eat and talk without difficulty on the morning after operation. Before and after such an operation, which in some cases has seemed to be coincident with the entrance of organisms into the blood stream, salicylates may be given, perhaps with greater security.

#### THE NEW ENGLAND TUBERCULOSIS CONFERENCE.

At the recent New England Tuberculosis Conference, held October 12 and 13, at New Haven, delegates representing all the New England States, and others to the number of nearly 300, were present. The atmosphere of this conference was a distinctly medical one, and as such, to those interested in the tuberculosis campaign, was very encouraging. There has been an evident and growing tendency on the part of the medical profession, and especially so on

the part of social workers, to regard tuberculosis as no longer a medical problem, but a social and economic one. While to a certain extent this is true, and while the social and economic aspects of this disease must receive careful consideration, fundamentally, however, we believe that the medical side of the problem is most important. That this is coming to be regarded the prevailing opinion in Massachusetts is shown by the fact that the Massachusetts Medical Society, for the first time, sent delegates to this conference. The Suffolk District Society and certain others, likewise, sent delegates. The State of Massachusetts was represented by the Trustees of Hospitals for Consumptives, the superintendents of the four State sanatoria, and others. There was present a surprisingly large number of general practitioners and of other physicians who are not ordinarily greatly interested in the tuberculosis campaign. As the early diagnosis of this disease rests almost wholly with the general practitioner, the presence of so many at this conference was an encouraging sign. It is to be hoped that the Massachusetts Medical Society will come to take an increasing interest in this disease and its prevention, and to realize that through its members, largely composed of general practitioners throughout this Commonwealth, the solution of the tuberculosis problem, in a large part, rests.

#### PROGRESS OF POLIOMYELITIS.

During the past week the epidemics of poliomyelitis have declined throughout the United States. On October 29 the number of cases in Massachusetts reached a total of 647 during the current month. On October 22 there were 58 cases in Quincy, and on October 26, 97 in Holyoke, with 21 deaths. Since January 1 there have been 1660 cases in Massachusetts.

Since July 1, there have been 420 cases and 117 deaths from this disease in Boston; and 90 cases with 15 deaths in Providence, R. I.

The weekly report of the United States Public Health Service for October 20, 1916, shows that from July 1 up to October 15 there had been 3917 cases in New Jersey, 3497 in New York State, exclusive of New York City, 1561 in Pennsylvania, 1127 in Massachusetts, 812 in Connecticut, 784 in Minnesota, 719 in Illinois, 428 in Michigan, 400 in Ohio, 361 in Wisconsin, and 254 in Maryland.

In the issue of the *Journal of the American Medical Association* for October 21, is published a preliminary note by Dr. E. C. Rosenow of Rochester, Minn., Dr. E. B. Towne of Boston, and Dr. G. W. Wheeler of New York, on the etiology of epidemic poliomyelitis. After reviewing the earlier work of Flexner and others on the isolation of the causative organism of the disease, they report the isolation from the throat, tonsils and central nervous system in cases of poliomyelitis of a peculiar streptococcus. By intravenous and intracerebral injections of cultures of this organism they have produced paralysis in animals of various species and have recovered the organism in pure culture from their nervous system. The symptoms and lesions produced are characteristic of poliomyelitis. The relation of this organism to that demonstrated by Flexner cannot yet be definitely stated, but the authors believe that the two may represent polymorphous forms of the same cocci under varying cultural conditions.

There is no further recent advance in the treatment of the disease. The Harvard Infantile Paralysis Commission has recently reported that of the cases in which therapeutic blood serum has been employed, none has completely recovered from paralysis, but only two have died.

#### MEDICAL NOTES.

**TEETH OF RURAL SCHOOL CHILDREN.**—A recent investigation made by the U. S. Public Health Service, in connection with studies of rural school children, showed that 49.3 per cent. had defective teeth, 21.1 per cent. had two or more missing teeth, and only 16.9 per cent. had had dental attention. Over 14 per cent. never used a tooth brush, 58.2 per cent. used one occasionally and only 27.4 per cent. used one daily.

**PREVALENCE OF DISEASE IN THE UNITED STATES.**—The weekly report of the United States Public Health Service for October 20, 1916, states that during the month of September there were reported in Maryland, 49 cases of malaria and 575 of typhoid fever. During the same period there were 80 cases of typhoid in Wisconsin and 16 of cerebrospinal meningitis and 373 of typhoid in Massachusetts. During the month of August there were in Virginia 2069 cases of malaria, 40 of pellagra and 1,107 of typhoid. There were 475 cases of typhoid in Kansas in August.

**GERMAN DEATH RATE.**—Report from Berlin on October 21 states that whereas in 1913 the German death rate was only 14 per thousand, the rate in 1914 was 16.1, in 1915, 19.7, but for the first seven months of 1916 fell to 16. These effects are attributable almost wholly to the war. Notwithstanding this, however, the infant mortality, which in 1912 was 14.1 per hundred new births and 15.6 in 1913, dropped in 1914 to 14.5 and in 1915 to 12.9.

#### EUROPEAN WAR NOTES.

**SALE OF TETANUS ANTI-TOXIN.**—Report from New York on October 19 states that since the outbreak of the European War the health department of New York City has sold to the allied powers nearly \$106,000 worth of anti-toxin, chiefly for tetanus. A very small amount has been sold during this period to the central powers, who have manufactured their own supply.

**MEDICAL UNIT FOR PALESTINE.**—Report from New York on Oct. 19 announces that arrangements have been made by the Zionist Committee of that city to send a medical unit of ten physicians and five nurses to Palestine, aboard the Syrian relief ship soon to sail from New York under the auspices of the Red Cross. The consent of the United States Department of State has been obtained for this purpose and it is planned, after landing the unit at some Mediterranean port, to transfer its members to Palestine aboard a United States warship. The purpose of the unit is to undertake the care of patients with typhus fever and Asiatic cholera, which are now epidemic in Palestine.

**AMERICAN RELIEF COMMITTEE FOR GERMAN BABIES.**—Report from New York on October 10 states that the American Relief Committee for German Babies, which was organized in Berlin at the outbreak of the war, by Americans resident in that city, now has about 1200 babies under seven years of age in its care. The beneficiaries are selected by the committee and the funds distributed by the German Red Cross.

The only beneficiaries of this fund are widows and orphans of soldiers slain in battle. Having chosen the family, the chairman of the American Committee, himself an American, directs the Red Cross there to make a monthly payment of \$40, and an effort is being made to pension each family for a full year.

Recent reports received at the main office of the Committee, No. 13 Park Row, New York City, show that the scheme is working out to perfection. The Berlin Red Cross has expressed its thanks, and those of its beneficiaries on more than one occasion through the medium of the wireless.

The American Relief Committee is a nationwide organization, of which George B. McClellan, former mayor of New York, is national

chairman, and John D. Crimmins, national treasurer. An additional office is maintained in Chicago at No. 220 South State Street, where Frederic W. Upham is chairman, and Charles G. Dawes, president of the Central Trust Company of Illinois, is treasurer. Members of the committee pay all operating expenses and funds donated are transmitted without deduction to the other side.

The committee has so far raised approximately \$50,000 and transmitted it by wireless to the other side, and no less than four hundred families are under its constant care."

#### MEXICAN NOTES.

**NEW RED CROSS BUREAU IN NEW YORK.**—To facilitate the dissemination among Red Cross chapters of information about the needs of European War sufferers, the American Red Cross has established a special information bureau in the Metropolitan Tower, New York, under the charge of Mr. Albert W. Staub, Superintendent of the Red Cross Receiving and Shipping Station at the Bush Terminal, Brooklyn. Mr. Staub will fill the two offices. His experience during the past two years as head of the Receiving and Shipping Station, and the steady correspondence which his office has with the receiving and forwarding representatives of various recognized relief agencies in Europe, will enable him to keep the more than two hundred Red Cross chapters in this country constantly advised as to the needs of the foreign Red Cross societies and representatives.

**STATUS OF A RED CROSS BASE HOSPITAL UNIT.**—The twenty-five Red Cross base hospitals, which have been organized or are being organized under the Department of Military Relief of the American Red Cross, have a strictly war-time purpose and are not generally available for use for civilian relief after disasters other than war, according to a Red Cross circular just issued. It says:

"Attention has been invited by the director of a Red Cross Base Hospital Unit to a misconception of the purposes of this military unit, in that a statement has been made that it would be available for purposes of civilian relief in great disasters other than war.

"This is an error, as base hospitals are purely military units, organized at the request of the Medical Departments of the Army and Navy, and equipped with a view to the needs of the military service only. In both organization and equipment they are too massive and too immobile for civilian relief work. The muster-in pledge contemplates only national service, when called into the military service of the United States; and it has been decided by the Judge Advocate General of the Army that the law does not authorize the calling out of these units by the President except in time of war or when war is imminent.

"It can be well imagined that in time of great national disaster, such as an earthquake, which involves injuries to large numbers of people, the staff of a base hospital unit might volunteer as *individuals*, and the American Red Cross would not hesitate to use the blankets, surgical dressings, and such other parts of a base hospital equipment as might be suitable for first-aid work to relieve an emergency. These supplies would, however, be regarded as a loan, and would be promptly replaced, if possible, from funds contributed to relieve the disaster. There would be no calling out of the unit as a unit, under these circumstances, and no compulsion on any member of it to volunteer."

**WAR RELIEF FUNDS.**—On October 28 the totals of the principal New England relief funds for the European War reached the following amounts:—

Belgian Fund .....	\$161,327.07
French Wounded Fund .....	130,059.27
Serbian Fund .....	101,649.07
Armenian Fund .....	80,705.05
French Orphanage Fund .....	67,906.91
British Imperial Fund .....	67,742.91
Surgical Dressings Fund .....	54,392.66
Polish Fund .....	46,620.83
Belgian Tobacco Fund .....	40,668.76
Permanent Blind Fund .....	19,004.12

#### BOSTON AND NEW ENGLAND.

**WEEK'S DEATH RATE IN BOSTON.**—During the week ending Saturday noon, Oct. 28, 1916, the number of deaths reported was 227, against 180 for the same period last year, with a rate of 15.57, against 12.54 last year. There were 38 deaths under one year of age, against 34 last year, and 66 deaths over 60 years of age, against 39 last year.

The number of cases of principal reportable diseases were: diphtheria, 48; scarlet fever, 18; measles, 4; whooping cough, 6; typhoid fever, 5; tuberculosis, 37.

Included in the above were the following cases of non-residents: diphtheria, 9; scarlet fever, 6; typhoid fever, 1; tuberculosis, 37.

Total deaths from these diseases were: diphtheria, 1; measles, 1; whooping cough, 1; typhoid fever, 1; tuberculosis, 19.

Included in the above were the following deaths of non-residents: tuberculosis, 2.

**ST. LUKE'S GUILD.** The annual meeting of St. Luke's Guild, held recently at the Carney Hospital, South Boston, was attended by over fifty members. Dr. John T. Rottenley was elected president for the ensuing year, Dr. John R. Slattery vice-president, and Dr. John J. Sullivan, secretary and treasurer.

**CHARLESGATE HOSPITAL TRAINING SCHOOL.**—The first graduation exercises of the Charlesgate Hospital Training School for Nurses were held recently in Cambridge under the presidency of Dr. George Bates. Diplomas were awarded to a class of ten pupil candidates.

**'CONSUMPTIVES' HOSPITAL CLINIC.**—It is announced that the clinic for the study of tuberculous cases which, for some time, has been conducted at the Maverick Dispensary, East Boston, jointly by the Dispensary, the Consumptives' Hospital Department and the Boston Association for the Relief and Control of Tuberculosis, will hereafter be conducted by the Consumptives' Hospital Department alone.

**MILK DEALERS' ASSOCIATION.**—The annual convention of the International Milk Dealers' Association, held in Springfield, Mass., on October 17, was attended by over 150 delegates. The leading address was by Dr. John Lovett Morse on "Milk for Infants."

"Approximately 300,000 babies die in the United States annually. If that number of infants die each year there are many millions of sick babies. A large percentage of the deaths is due to poor milk, which comes from diseased cows.

"Of the total number of cases there are about 1500 deaths a year from tuberculosis which can be traced to milk from the dairy cow. The only way to protect the public health from such diseases as tuberculosis, typhoid fever, diphtheria, sore throat and scarlet fever is by pasteurizing the milk from the cow.

"The sooner the milk dealers of this country realize that it lies within their power to save the lives of infants, fewer babies will die. The question of reducing infant mortality, in other words, is directly up to the milk dealers, who should speedily adopt measures to safeguard the public health."

Other addresses were delivered by Mr. James O. Jordan on "A Municipal Milk Supply," and by Professor W. B. Frost of the University of Wisconsin on "Milk Bacteria Count and Microscopic Test for Pasteurized Milk."

### Miscellany.

#### AMERICAN SOCIETY FOR THE CONTROL OF CANCER.

THE American Society for the Control of Cancer has recently issued the following report of its organization and activities as presented to the various special societies at the Congress of American Physicians and Surgeons held in Washington in May, 1916. The Cancer Control Society having been formed under the direct auspices

of these national medical organizations at the Congress of 1913, the present report was submitted as a summary of progress during the intervening three years in the effort "to disseminate knowledge concerning the symptoms, diagnosis, treatment and prevention of cancer, to investigate the conditions under which cancer is found and to compile statistics in regard thereto."

#### REPORT TO THE CONGRESS OF PHYSICIANS AND SURGEONS, MAY, 1916.

At the ninth meeting of the Congress of American Physicians and Surgeons held in Washington in May, 1913, the American Gynecological Society presented to the other branches of the Congress an identical resolution requesting the appointment of two or more delegates to co-operate in forming a national organization to conduct educational propaganda regarding the prevention and cure of cancer. The Gynecological Society had just adopted the report of its committee which had been at work on this problem for a year or more previously, and had recommended that a special society should be established with the sole purpose of conducting this much-needed campaign of education and the collection of data on a nation-wide basis and on a general plan similar to that of the National Association for the Study and Prevention of Tuberculosis. In preparing its report and recommendation the committee of the Gynecological Society had secured the interest and promised support of a group of lay citizens of New York, five of whom, Messrs. John E. Parsons, V. Everit Macy, James Speyer, Thomas W. Lamont, and George C. Clark, had guaranteed \$5,000 toward the first year's expensess of the proposed organization, but solely on condition that the project be approved, not only by the Gynecological Society, but by the profession generally.

A majority of the constituent societies of the Congress promptly responded to the suggestion of the Gynecological Society and the following delegates were appointed:

- (1) American Dermatological Association: Dr. S. Pollitzer, Dr. M. F. Engman.
- (2) American Surgical Association: Dr. George Brewer, Dr. Joseph Bloodgood, Dr. Charles L. Gibson.
- (3) American Laryngological Association: Dr. George B. Wood, Dr. J. Gordon Wilson.
- (4) American Otological Society: Dr. Charles W. Richardson, Dr. George E. Shambaugh, Dr. Christian R. Holmes.
- (5) American Association of Genito-Urinary Surgeons: Dr. H. A. Fowler, Dr. F. R. Hagner.
- (6) American Gynecological Society: Dr. Reuben Peterson, Dr. Edward Reynolds, Dr. Thomas S. Cullen, Dr. Frank F. Simpson, Dr. William E. Studdiford, Dr. Frederick J. Taussig, Dr. Howard C. Taylor, Dr. LeRoy Broun.

- (7) American Association of Pathologists and Bacteriologists: Dr. A. S. Warthin, Dr. James Ewing.
- (8) American Orthopedic Association: Dr. Reginald H. Sayre, Dr. J. D. Griffith.
- (9) American Ophthalmological Society: Dr. Richard A. Reeve, Dr. F. E. Cheney, Dr. Hiram Woods.
- (10) American Neurological Association: Dr. Harvey Cushing, Dr. B. Sachs.

These delegates were invited to a meeting at the Harvard Club in New York City on May 22, 1913, at which time the American Society for the Control of Cancer was duly organized and the following declaration of its design and scope embodied in the constitution:

"To disseminate knowledge concerning the symptoms, diagnosis, treatment, and prevention of cancer, to investigate the conditions under which cancer is found and to compile statistics in regard thereto."

It is but fitting that a movement which traces its origin and so large a part of its prestige with the profession and public to the Congress of 1913 should present on this occasion an acknowledgment of indebtedness to all the co-operating organizations and make some account of methods of work and progress during the last three years.

**Plan and Scope.**—The purpose of the Society as just stated prescribes two main lines of activity: (1) a campaign of public and professional instruction, and (2) the collection of statistical data. Experimental research, the support of hospitals or clinics, and the care and treatment of individual patients are not contemplated. In extending its influence and carrying on its work, the Society necessarily devotes a large share of its direct efforts to securing the interest of other organizations and forces which are in a position to render assistance in local fields.

**Professional Endorsement.**—In the months immediately following the formation of the Society under the auspices of this Congress, other prominent professional bodies successively recorded their approval and support of the project. Resolutions of endorsement have been adopted by the American Medical Association, the Clinical Congress of Surgeons, the Western Surgical Association, the Southern Surgical and Gynecological Association, and many state and local medical societies.

**Executive Control.**—The government of the Society is vested in a Board of Directors which numbers 66 members, including practitioners of recognized standing and prominent and interested lay men and women from many parts of the country. The direction of the work in detail is delegated to an Executive Committee of thirteen Directors including the chairmen of standing committees on organization, membership, finance, publication, and statistics. The professional members of the Board act in conjunction

with the Executive Committee as an Advisory Council which formulates the general policies of the Society.

**Membership and Finance.**—In so far as paid service is necessary to supplement the volunteer work, which is the chief source of the Society's vitality, a modest budget is raised entirely from dues of members at five dollars per annum and from special contributions in larger amounts. The Society has no endowment and no fixed income from any philanthropic foundation. At present there are 577 members and contributors of all classes, approximately half of whom are physicians, the list including some of the leading American practitioners. The interest and support of these doctors is a chief asset of the Society and this opportunity is taken to urge every member of the Congress of Physicians and Surgeons to contribute his influence by becoming an annual member.

**State and Local Committees.**—Branch committees of the Society are formed in the several states and cities, not as independent local organizations, but as integral parts of the single National Society. The chairmen of state committees are usually members of the National Board of Directors and are vested with full power to appoint the other members of their committees and supervise their work. State committees in turn may organize local committees in the principal centers of population wherever the interest and needs warrant. At the present time state committees have been authorized in sixteen states and several others are in the process of formation.

**Organization and Cooperation.**—The Society has considered it a matter of first importance to develop its National Executive Office as a central bureau and clearing house through which to seek the coöperation of all appropriate general and local agencies, and to receive and transmit impulses tending to further the propaganda of public instruction in all parts of the country. Standing in close relation, on the one hand, to the leading experimental and statistical students of the disease who represent sources of new and old knowledge of the subject, the Society is, on the other hand, in helpful contact with the various social forces which can be called upon to transmit the essential facts to the public.

**Boards of Health.**—Widespread and increasingly effective work is being done by state and city boards of health in the direction of instructing the public regarding the prevention of disease. The Society therefore endeavors to have the more progressive health officers devote a proportionate share of attention to cancer in this connection, and the national office undertakes to furnish data, statistics, and special articles produced under the supervision of the appropriate committees, for local use in the name of the board of health. Many health boards, including particularly those of Michigan, Vir-

ginia, North Carolina, New York, Massachusetts, Kansas, New York City and Toronto, are now taking an active part in this campaign, while a number of other departments have made a beginning.

*Medical Societies and Education of the Profession.*—The design of the Society is taken to include efforts to keep the general practitioner in touch with the latest developments in the knowledge of cancer, and cognizant of his duty to the patient. In this field, however, it is felt that the regular professional organizations should take the lead. The Society, therefore, offers all possible coöperation and assistance to state and county medical societies in providing literature and speakers, and to the various medical journals in publishing appropriate articles. Many state societies have appointed special cancer committees, some of these, as in the case of Pennsylvania, antedating the formation of the national organization and representing notable pioneer work in this field in America. In several instances the committee of the National Society and that of the state medical society have been made identical. The existing state committees on health and public instruction have also been approached with reference to the inclusion of cancer in their programs.

*Nurses.*—Systematic effort is made to promote the instruction of nurses regarding the earlier phases of malignant disease and predisposing conditions, in order that they may be adequately prepared to advise people, especially women with whom they come in contact in the course of their duties, to seek professional attention in time. A series of special articles for nurses has been published, meetings for nurses have been arranged, all the leading schools of nursing in the country have been urged to include in their courses lectures on the early signs and symptoms of cancer, and opportunities are sought to present the subject at the annual meetings of state and national organizations of nurses, a number of which have recorded their endorsement of the purpose and methods of the Society.

*Social Workers.*—The field workers of charity organization societies have similar opportunities to advise people who do not ordinarily read newspapers and educational books and pamphlets. The National Office has, therefore, circularized several hundred of the larger charity organization societies in the various states, seeking their interest and coöperation in holding public meetings and in arranging for the special instruction of the members of their working forces.

*Women's Clubs.*—Women's organizations have proven one of the most effective single agencies in disseminating knowledge of early cancer and the conditions leading to the disease. The work of the Society has been brought to the attention of the national and state federations of women's clubs, and the appropriate committee officials have been circularized in or-

der to secure their coöperation in suggesting this topic to local clubs. As a result, women's clubs in many states and cities have frequently taken the lead in arranging public meetings and in providing lectures in their regular study programs.

*Insurance Companies.* The coöperation of the leading insurance companies is sought, not only in respect to statistical investigations, but for the distribution of educational literature. One of the largest companies has reprinted, at the suggestion of the Society, a cancer leaflet which it is prepared to distribute to the number of two million copies. At the recent meeting of the American Life Convention a resolution was adopted providing for the distribution by insurance companies generally of a brief uniform circular, approved by the Society, to be sent out in premium notice envelopes, thereby reaching many thousands of intelligent people. The Life Extension Institute, which grew out of the educational work of insurance companies, has advised its subscribers regarding the early recognition of cancer, and is indirectly furthering the campaign by its propaganda for periodical physical examinations.

*Industrial and Welfare Organizations.*—Many of the larger industrial, commercial, and transportation companies have undertaken extensive welfare work and health instruction for the benefit of their employees. The Society has offered to the appropriate officials of these companies any desired assistance in providing speakers and circulars, or suggestions for the preparation of special literature to be distributed by the companies themselves. In this connection the coöperation of such organizations as the National Civic Federation, the National Safety Council, and the American Museum of Safety has been invited.

*Newspaper Publicity.*—By direct effort and through its local committees and various other agencies already referred to, the Society stimulates the publication of carefully considered newspaper articles. So far as possible, the character of this matter is controlled by the national organization, which sends out in its own press service short articles prepared under the close scrutiny of a committee on publication, made up of professional men of recognized standing. From the beginning, the Society has also had the benefit of the constant advice and coöperation of the Council on Health and Public Instruction of the American Medical Association, and by special arrangement a cancer article has been supplied for each issue of A. M. A. press service, which reaches a selected list of several thousand newspapers. Valuable newspaper publicity has also been secured through the work of some of the leading state and city boards of health, whose statements to the editors on this topic are frequently given better attention and more space than articles sent out by a distant national bureau.

**Circulars and Bulletins.**—The Society has published for general distribution to the public a number of leaflets giving in simple language the elementary facts about the disease. These circulars are distributed directly on request to the central office or indirectly through local committees. Arrangement has been made to provide these or other approved circulars at small cost to boards of health and other local organizations in a position to purchase and distribute such material.

A series of special bulletins is also published for more limited distribution among members of the Society and those who are directly concerned in organizing local educational campaigns.

**Public Meetings and Lectures.**—To inaugurate work in each of the more important cities, the coöperation of professional, civic, and religious forces is secured in arranging a general public meeting, at which recognized experts may discuss the various phases of the cancer problem. Perhaps even more effective in reaching the public with the facts are lectures given under various auspices, particularly women's clubs, to small audiences under conditions such that a single speaker can present the subject in a more direct and convincing manner. It is a particular function of local committees to arrange for such lectures. The Society, through its national and branch offices, undertakes to act as a lecture bureau and to provide qualified speakers for meetings in any part of the country.

**Statistical Research.**—The second principal object of the Society is to organize statistical research on a broader basis than has hitherto been possible. While numerous individuals, clinics, research laboratories, insurance companies, and public health departments have been interested in this field and have done valuable independent work, the Society has now undertaken to coördinate all these agencies for the conduct of special investigations on a larger scale. To this end a Statistical Advisory Board has been formed, which includes thirty representatives of the leading American organizations in the several classes referred to.

**National Mortality Statistics.**—At the suggestion of the Society the Director of the United States Census has ordered the publication of a special report on the cancer mortality of 1914, which is now in press, and will constitute one of the most important statistical studies of this disease so far made under the auspices of any government. An important advance undertaken in this connection, at the suggestion of a prominent American surgeon, is the distinction made between the figures of deaths in which the diagnosis was reached after autopsy, surgical intervention, or microscopical examination, and those in which the diagnosis was based merely on clinical observations. In addition, the forthcoming report will give the figures in far greater detail than hitherto, and according to 29 separate organs and parts of the body affected instead of

under the seven group titles of the International List of Causes of Death as used in the annual reports of the Census Bureau. Much of the improvement with respect to greater detail and accuracy which characterizes this special report will, doubtless, become a permanent feature of the American national statistics of cancer.

**Operative Statistics.**—The Society has also undertaken the collection and study of records of operations for cancer in numbers approximately as great as those represented in the national mortality statistics. A blank has been prepared by a sub-committee of the Statistical Advisory Board, and leading surgeons throughout the country are asked to coöperate in this study by reporting thereon a few essential facts regarding each case of the disease on which they operate, either in private practice or in hospital service. The records thus obtained will be followed up at intervals of one year by inquiry addressed to the surgeon, and the data will be tabulated and analyzed by expert statistical methods. Any new and definite evidence as to the curability of cancer which may result will be laid before the public in the course of the educational campaign, but any such announcement will be in the name of the Society, and no comparison or publication of the work of individual surgeons will be authorized.

**Hospital Records.**—The committee on statistics has also prepared a series of more detailed blanks, one for each principal type of malignant disease, on which to record the full history of cases as a basis for careful study of etiological factors. These forms have been put into experimental use, and when perfected will be offered for use in a number of the larger hospitals in the endeavor to bring out important factors surrounding the occurrence of cancer in the individual, in the family, and in the community.

## Correspondence.

### AN ERROR OF QUOTATION

DORCHESTER, MASS., OCTOBER 5, 1916.

MR. EDITOR: Permit me to call to your attention a slight error in quotation and in authorship. I refer to "In medio tutissimus ibis," which occurs in Dr. F. Fremont-Smith's paper in *Boston Medical and Surgical Journal* of October 5, 1916. The line is from Ovid's *Metamorphoses*, II, 137, and not from Virgil.

The complete verse reads: "Inferius teras, medio tutissimus ibis."

Very sincerely,

WAL. B. BATHURST, M.D.

[NOTE.—This quotation occurred correctly in the issue of the *Journal* for June 10, 1915 (Vol. CLXXII, p. 849). Had the proof of the present article been more carefully read, the error would probably have been detected in this instance. —EDITOR.]

# CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE THREE WEEKS ENDING OCTOBER 11, 1916.

September 22.

Surgeon H. F. Strine, to Naval Hospital and School, Washington, D. C., September 25, 1916.

Surgeon R. W. Plummer, to *Alabama*.

Surgeon G. F. Freeman, detached *Tacoma* to home, wait orders.

P. A. Surgeon H. A. May, detached Marine Barracks, Port Royal, S. C., to home and wait orders.

P. A. Surgeon P. E. Garrison, detached *Dolphin* to duty with Expeditionary Forces in Santo Domingo.

P. A. Surgeon E. H. H. Old, detached Naval Hospital, Washington, D. C., to *Solace*.

P. A. Surgeon D. G. Allen to *Chester*.

September 22.

Surgeon H. C. Curl, detached Force Surgeon, Reserve Force Atlantic Fleet, to Marine Barracks, Port Royal, S. C.

P. A. Surgeon G. B. Tribble, to Naval Academy, Annapolis, Md., Sept. 25.

September 23.

P. A. Surgeon E. R. Huff, detached *Scorpion* to home and wait orders.

September 25.

Surgeon C. D. Langhorne, resignation accepted from Sept. 29, 1916.

P. A. Surgeon D. H. Noble, to Naval Hospital, Philadelphia, Pa.

Asst. Surgeon J. H. Brantley, commissioned from August 26, 1916.

Asst. Surgeon A. H. Cecha, commissioned from Aug. 29, 1916.

Asst. Surgeon I. W. Jacobs, commissioned from Aug. 26, 1916.

Asst. Surgeon P. F. Prioleau, commissioned from Aug. 29, 1916.

Asst. Surgeon F. T. Power, commissioned from Aug. 28, 1916.

October 4.

Surgeon C. E. Triebly, detached *North Dakota* to *Illinois*.

Medical Director George B. Wilson died at Boston, Mass., Oct. 1, 1916.

Asst. Surgeon John Harper, detached *Minnesota*, to connection fitting out *Arizona*, and duty on board, when commissioned.

October 5.

Surgeon J. S. Taylor, detached *Rhode Island*, to *Connecticut*.

Surgeon C. G. Smith, detached Bureau of Medicine and Surgery, Navy Department, to fitting out *Arizona*, and on board when commissioned.

Surgeon J. A. Murphy, detached *Michigan*, to Bureau of Medicine and Surgery, Navy Department, Washington, D. C., Oct. 14, 1916.

Asst. Surgeon R. L. Crawford, detached *Connecticut* to *Rhode Island*, Oct. 5.

Medical Director Philip Leach, detached Naval Hospital, New York, to command Naval Hospital, Boston, Mass.

Medical Inspector G. A. Lung, detached Naval Torpedo Station, Newport, R. I., to command Naval Hospital, New York.

Surgeon H. C. Curl, to *Michigan*.

P. A. Surgeon G. R. W. French, detached *Maine*, to Torpedo Station, Newport, R. I.

October 6.

Surgeon H. D. Wilson, to home and wait orders.

P. A. Surgeon J. B. Mears, detached *Memphis*, to Expeditionary Force, Santo Domingo.

## ARMY MEDICAL CORPS EXAMINATION.

The Surgeon-General of the Army announces that preliminary examination for appointment to first lieutenants in the Army Medical Corps will be held early in January, 1917, at points to be hereafter designated.

Full information concerning this examination can be procured upon application to the "Surgeon General, U. S. Army, Washington, D. C." The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, between 22 and 32 years of age at time of receiving commission in Medical Corps, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, of good moral character and habits, and shall have had at least one year's hospital training as an interne, after graduation. Applicants who are serving this post-graduate internship and can complete same before Oct. 1, 1917, can take the January examination. The examination will be held simultaneously throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible.

In order to perfect all necessary arrangements for the examination, applications should be forwarded without delay to the Surgeon General of the Army.

There are at present two hundred and twenty-eight vacancies in the Medical Corps of the Army.

## NOTICES.

**HARVEY SOCIETY LECTURES.**—The second lecture of the current twelfth course before the Harvey Society will be given at the New York Academy of Medicine on Saturday evening of this week, November 4, by Dr. F. M. Allen of the Hospital of the Rockefeller Institute on "The Role of Fat in Diabetes."

**SUFFOLK DISTRICT MEDICAL SOCIETY, CENSORS' EXAMINATION.**—The censors of the Suffolk District Medical Society will meet to examine candidates for admission to the Massachusetts Medical Society at the Boston Medical Library, 8 The Fenway, on Thursday, November 9, at 4 P. M.

Candidates, who must be residents of the Suffolk District or non-residents of Massachusetts, should make a personal application, at least three days before the examination, to the Secretary, at 355 Marlborough street, between 4 and 5 o'clock, P. M. (except Saturdays and Sundays), and present their medical diplomas.

DAVID CHEEVER, Secretary,  
Suffolk District Medical Society.

## APPOINTMENTS.

**HARVARD MEDICAL SCHOOL.**—Dr. Edward H. Nichols and Dr. Charles A. Porter, formerly associate professors of surgery in the Harvard Medical School, have been appointed clinical professors. The following appointments as assistants have been confirmed: Dr. Donald M. Glover, assistant in histology; Dr. Joseph H. McGuire, assistant in histology; Dr. Maelver Woody, assistant in pathology; Dr. Harry S. Bernstein, assistant in pathology; Dr. Francis L. Burnett, assistant in pathology; Dr. George Clymer, alumni assistant in neurology; Dr. LeRoy C. Gardner, instructor in pathology.

## RECENT DEATH.

DR. D. BRADYEN KYLE, who died of pneumonia, on Oct. 23, at Philadelphia, was born at Cadiz, O., in 1853. He received the degree of M.D. from the Eclectic Medical College of Cincinnati, Ohio, in 1891. He was known as a specialist in rhino-laryngology, and has written several text-books on diseases of the nose and throat. He was formerly president of the American Laryngological Association.

## Therapeutic and Preventive Medicine.

### TREATMENT OF WEAK LABOR PAINS.\*

BY STEPHEN RUSHMORE, M.D., BOSTON.

THE subject of weak labor pains is one in which both the specialist and the general practitioner are interested. It is a timely one for consideration, I think, because of the present indiscriminate use of two means of assisting the unavailing efforts of the woman in labor to deliver herself of her child on schedule time. These are the extract of the pituitary gland and Cesarean section. In the past the obstetrical forceps has come in for its share of condemnation, but I think it has fallen somewhat into disuse now that the other methods have come into vogue.

Before discussing whether weak labor pains need any treatment, and, if treatment is indicated, when it should be instituted and how it should be carried out, it may not be out of place to recall some of the features of normal labor for purposes of comparison. Perhaps, by a consideration of the mechanism and physiology of normal labor, some light may be thrown on the pathological condition.

By the term "labor," we mean the effort of the female organism to separate from itself the products of conception. This effort, though largely involuntary in character, is not unconscious, but is accompanied by sensations of a disagreeable nature so acute and severe that

they are called pains. So far as we know, labor is always painful among the higher mammals; the few exceptions are of interest as curiosities rather than as indicating a normal condition from which painful labor is a pathological deviation. To be sure the process seems to make greater demands on the individual in the higher forms, and among human females, the more highly civilized are more subject to difficulties of labor, of one sort or another.

Labor, terminating the period of gestation, comes on in the human female about two hundred and eighty days from the appearance of the last menstruation. But, if ovulation occurs about midway between the beginnings of two menstrual periods, as seems probable, conception takes place no less than two weeks from the beginning of the last menstruation, and gestation is more nearly two hundred and sixty-five days. But gestation is not always terminated on this two hundred and eightieth day, and while the well known rule for computing the date of confinement gives the day on which labor is most likely to begin, a week's variation in either direction is entirely normal.

When labor comes on, the uterus tries to expel its contents by contraction of the muscular fibres. These involuntary efforts recur at rather regular intervals, becoming stronger and more frequent. In time there are added voluntary contractions of the muscles of the abdominal wall and of the diaphragm, aiding in the expulsive effort. At first the contractions are manifest to the patient only as a drawing or tightening sensation, but later they are associated with pain, gradually becoming severe. During a painful contraction,

\* Read at a meeting of the Penobscot County Medical Society, April 18, 1916.

the pain comes on at a distinct interval after the contraction has begun, and is due to pressure of the presenting part and stretching of the cervical canal and the vagina as well as to the spasm of the muscle. For a long time three stages of labor have been recognized: (1) the stage of dilatation of the cervical canal until it is large enough to permit the passage of the fetus from the uterus; (2) the stage of expulsion, during which the fetus is expelled from the uterus and the vagina is dilated; it is terminated by the birth of the child; and (3) from the birth of the child to the expulsion of the placenta.

Of the nervous mechanism we know little except in a general way. The uterus is abundantly supplied with nerves and ganglia and can carry on its usual function separated from the central and sympathetic nervous systems, as is shown by experiments on the isolated pregnant uterus of animals. Clinical observations have shown that complete transverse section of the spinal cord does not interfere with labor except in so far as it prevents the contraction of the abdominal muscles. That psychic influences may play a part is well known, but in general the central nervous system has only a regulating function. There may be, and probably are, several centres in the cord from which reflex impulses may inhibit or accelerate labor, but of them we actually know very little.

Experience has shown that the computed date for confinement, two hundred and eighty days after the appearance of the last menstruation, is about the best time for the infant to be born. If it is born much before this date, it is underdeveloped and not likely to live. If born much after this date, not only is the child larger and thus likely to cause more difficulty during birth, but for reasons of which we know nothing its vitality is often found to be reduced, even if birth has been normal and easy. How does the maternal organism know when to fall into labor, and how does it know what is the best time for the child to be born?

Explanations of the cause of labor are numerous and date back to antiquity. Some of them are fanciful and need only to be stated to show their error. Others are more reasonable, but must await further investigation for a final judgment as to their validity. In certain cases of labor before term, we find disease of the placenta, or of the decidua, overdistention of the uterus, or trauma, which may have been the cause of the incidence of labor in that particular case, but in normal labor at term no such factors are present. We might make an exhaustive study of the ways in which labor can be induced, and comparing the changes which occur with the changes in normal labor might find a suggestion as to the usual cause. But this has not yet been done.

One constant fact we have as a basis. There is in pregnancy a growing irritability of the uterus, and with it an increase in frequency and

strength of the intermittent contractions known as pregnancy contractions. But of the cause of this we know nothing. Another characteristic of the pregnant uterus is that if strong contractions are started from any cause, they tend to continue until labor is ended. At the present time, when we are finding the long-looked-for explanation of so many phenomena of living organisms by the help of the finer chemistry, it is natural that the suggestion should be made that some substance circulating in the maternal blood should be the cause of labor pains, and experimental investigations bear this out, though only a beginning of study along these lines has been made. In the first place, experiments have shown that the connections with the central and sympathetic nervous systems are not necessary for labor. These and other experiments indicate that the cause of labor is a substance in the maternal circulation acting on the uterine muscle or on the intrinsic nerves of the uterus.

What is this substance and from what organ or structure does it come? Its nature is wholly unknown to us but its point of origin can be tested in a general way by injecting into animals, near term, extracts or blood from various sources. It has been found that injections of from twenty to fifty cubic centimeters of fetal blood into the vein of a pregnant woman at, or near term, will bring on labor in a few hours. The conclusion has been drawn that labor is due to a substance produced by fetal metabolism, accumulating in the uterus and giving rise to gradually increasing irritability.

While there is no reason, I think, for doubting the experimental facts, the conclusion may be open to certain objection. These experiments, and others which I will not take the time to describe, have established simply the facts that the substance or group of substances which produces labor is found in the fetal and in the maternal circulation. But as an interchange of substances between the two circulations is possible, the primary source of the stimulus is not clear.

The duration of labor depends on a number of factors which may be grouped under the following heads:

1. The force exerted by the uterus and by the abdominal muscles in dilatation and expulsion.
2. The application of this force, whether mechanically advantageous or disadvantageous. The vertex presentation with head well flexed and membranes unruptured gives an application of the force during dilatation of the cervix which is very advantageous. Malpositions of the fetus with ruptured membranes may give a very disadvantageous application.
3. The resistance of the maternal parts, which has to be overcome.
4. The size of the fetus.

The test of normal labor is that the woman should pass through this process without injury

to herself, and deliver herself of a normal child in approximately the same time as other women. It is a test which we can apply easily when labor is over, and which we can apply in a general way during labor, but we are quite at a loss before pains have started. While we can measure the pelvis and determine the position of the child, guess at its size and estimate the resistance of the soft parts, we have little accurate knowledge of these points and we can only be in doubt and ignorance when it comes to judgment as to that most important factor,—the strength of the uterus.

Efforts have been made to study the pains of labor with some exactness, measuring their force and duration and noting their character. The classic tokodynamometer of Selatz, a compressible bag introduced into the uterus and connected by a tube with a column of mercury, has proved very useful in spite of its limitations. But it is applicable only in special studies and is not suitable for routine procedures. Recently Fabre has described what he calls external hysterography, a method of automatically recording the contractions of the uterus during the course of pregnancy, labor and the puerperium. The apparatus is applied to the abdomen and the record is made by means of levers, a drum and revolving cylinders. It may be employed at any stage of labor and is not disturbed by respiration or by the fetal movements.

By this apparatus Fabre was able to get a better idea of the character and strength of labor pains than by palpation, timing the pains and noting the subjective symptoms of the patient. He was able to observe also the effect of drugs on the uterine contractions. He claims that the administration of chloral hydrate, ether and morphia, controlled by hysterography, will give marked diminution of the pain of labor, without interference with the muscular activity and without endangering the life of the fetus.

If a patient is in labor, how can the process be modified, either by increasing or diminishing the pains? Here the same factors by which labor may be induced come into consideration, but I shall only mention at this point some of the results of Fabre's studies of drugs in checking uterine contractions. Chloroform and ether cause a slight diminution in the force of the pains; chloral hydrate makes them more regular as well as diminishes the frequency. Morphia seems to diminish the intensity of the abnormally strong pains while scopolamin seems to cause a cessation of activity. These results have not yet been confirmed by other investigators using his method, but the method would seem to offer possibilities of considerable advance in the accuracy of our knowledge.

What do we mean by the expression, "weak labor pains"? The term is relative, for in the course of normal labor the pains are, at times, of little force and yet are perfectly normal, as, for example, early in the first stage and in the

third stage. Sometimes, too, in the first or second stage, the pains may show a marked remission in force, but they begin again with renewed vigor and continue until labor is terminated within the normal period of time. So that by weak labor pains we mean lack of force over a prolonged period or at a time when we should expect the pains to be forceful. They may occur in the first, second or third stage, and as uterine contractions continue after the expulsion of the placenta: a complete study would cover this period also, for post partum complications may develop as a result of weak uterine contraction.

Weak labor pains may be either primary or secondary. By primary, we mean those in which either the normal stimulus to contraction is weak, or the muscle itself does not react well. Of the normal stimulus to contraction we know very little, but if it is a substance from the fetus accumulating in the uterine wall and sensitizing the uterus, we can see how insufficient sensitizing might be a factor, at term or particularly before term. While this would explain certain cases of defective uterine contraction, there is little more than theory for a basis.

Of defective muscular development, a little more is known. Patients with delayed uterine development, or those who have passed beyond the highest development and are approaching the senium, or those who show developmental malformations, more frequently show anomalies of uterine contraction, which are perhaps due to defective development of muscle. Defective innervation may also play a part. It is my impression that the increasing difficulty which the modern civilized woman has with labor is due to defective hygiene during the period of adolescence, which has its effect not only on the nervous system, making women less capable of standing the strain of pregnancy and childbirth, but through underdevelopment of the genital system actually increasing the strain.

Primary weak pains are not at all infrequent and may be due not only to the causes mentioned, but to any factor affecting the general condition of the patient, as prolonged ill health from any cause, as well as to local disease which has reduced the strength of uterine muscle, once well developed.

By secondary weak pains we mean those which are weak having once been strong. This condition comes on because the muscle is tired from overwork. Here again we have a relative term, for what might be entirely adequate force under certain conditions is not enough if there is slight obstruction, or difficulty of delivery due to occiput posterior or breech, or slight disproportion between head and pelvis, or rigidity of the soft parts.

Now if we have a patient in whom the pains of labor are weak, according to our definition, that is, over a prolonged period or at a time when they ought to be strong, why should we do anything? Will not nature prove adequate

and will not the woman deliver herself in the course of time? The mere asking of this question brings clearly to the minds of all of us the sad memory of times when nature did not prove adequate and when in spite of such assistance as we could render, the mother as well as the child suffered greatly. But it does not give the answer as to when assistance is indicated, nor the kind of assistance that may be most appropriately rendered. These are determined by the stage of labor, the condition of the mother and the child and by the resources which we have at our disposal. I am taking it for granted that thorough examination has excluded as far as may be the presence of any gross anomaly of fetus or pelvis.

A consideration of the resources at our disposal will show what they can and cannot accomplish and thus the indications for their use. Among the resources are, briefly, rest, massage of the uterus, changes in position in bed and by walking, rupture of the membranes, dilatation of the cervix and the administration of drugs. Sometimes in normal labor we see the pains die down and, after an interval of apparent rest, start up again with renewed vigor and go on to the termination of labor. In certain cases after the onset of labor, when the pains are weak or have disappeared, the patient will rest or even sleep following the administration of chloral hydrate, morphia, or scopolamin and morphia, and on waking will complete labor with normal pains. This happy outcome may be expected only when the mother and fetus are in good condition and the inertia is manifest in the first stage of labor, when alone this treatment is justifiable.

Since certain mechanical stimuli increase the rate and force of uterine contractions, massage of the fundus is a rational method of treatment, but experience has shown that it does not accomplish what we want, producing only a single contraction while the stimulus is applied. The same may be said of changes of position in bed, turning the patient from side to side or from back to side. It may produce a few contractions, but that is all.

In the first stage we have all found that having the patient walk around the room is a useful and sometimes a perfectly adequate stimulus.

Occasionally early rupture of the membranes will give increased activity of the uterine contractions, but how it acts is not clear, and in general it does not accomplish much, and if the bag of waters is opened too soon the patient loses the benefit of the hydrostatic wedge in the dilatation of the cervix.

But what we want is a more certain method of inducing labor pains or stimulation to adequate activity if they are present but weak. This is found in forcible dilatation of the cervix. It is perhaps a part of the mechanism of normal labor, the increasing dilatation from pressure of the presenting part producing in-

creased uterine contractions. Two methods have been suggested in practice,—manual dilatation and dilatation with a bag, various forms of which have been employed by different operators. In either case an instrument may have to be used to start the dilatation, until the fingers can be introduced or until the bag can be placed in the cervix, but it is not always necessary.

Manual dilatation requires surgical anesthesia and is rapid and, therefore, more likely to give troublesome lacerations of the cervix. There is a certain increased risk from infection. It should be given up in favor of the bag except when rapid dilatation and immediate delivery are necessary. Here for primigravidae I personally prefer to replace it by another procedure of which I shall speak presently.

The type of bag which is perhaps most frequently used in this country is that suggested by Voorhees of New York. It is cone shaped with a tube attached to the apex of the cone, and is made in several sizes. It is made of linen or cotton fabric, covered on both sides with rubber, and is, therefore, watertight as well as inelastic. It is introduced in a collapsed condition, without an anesthetic, under primary ether, or preferably, under nitrous oxide or nitrous oxide and oxygen anesthesia, and filled with sterile water. The tube is then tied or clamped and the patient left alone. If labor does not come on promptly, or if there is reason for hastening labor, traction on the bag may be made by a weight hung over the foot of the bed. It is a most efficacious instrument and I know of only one objection to its use, namely, the possibility of introducing infection. But it would seem that careful technic would almost eliminate this danger, and I have never seen a case of infection following its use.

I have referred to those cases in which with weak uterine contractions and undilated cervix, immediate delivery becomes necessary in the interest of the mother or of the child. The possibilities are rapid dilatation of the cervix and extraction of the child by forceps or after version, and Cesarean section. The discussion of the indications for either procedure is outside of my province this evening, but I would simply call your attention to the advantages of the so-called vaginal Cesarean section, which is not a Cesarean section at all, over manual dilatation of the cervix.

The operation is to incise the cervix in the median line anteriorly and posteriorly, if necessary on both sides also, until an opening is obtained large enough to permit extraction of the child. The irregular lacerations following manual dilatation, extending an uncertain distance, are replaced by incisions made by a sharp instrument, and therefore, with less trauma, under constant supervision. Suturing after extraction is more easily accomplished. If necessary, incisions of the perineum are made and easily closed.

The last resource which I shall consider, and it is the last in the order of consideration and not in the order of use, is drugs. Among drugs which have been used to stimulate uterine contractions there might be mentioned many which have been tried, but were soon rejected. Recently there have been subjected to the test of practice salicylic acid, sodium borate, cannabis indica, strychnia, cola, cane sugar, milk sugar, digitalis and caffeine.

Certain oils have been recommended as emmenagogues and it is known that they will produce abortion; for example, oil of rue, of thyme, of turpentine, apiol, and sabine. The suggestion was made that under proper control they might be useful in stimulating normal uterine contractions. Careful tests of their action on the isolated uterine muscle of pregnant and non-pregnant animals have been made. It was found that they have a paralyzing action even when very dilute, so that they are to be regarded not only as of no value, but as positively dangerous in practice.

Noteworthy among the substances which have been given up after trial is pilocarpin which has a distinct oxytocic effect as shown by clinical experience as well as by laboratory experiments. Its use was begun about forty years ago and it was administered hypodermically during the period of dilatation. Troublesome symptoms, however, as salivation, possible unfavorable action on a weak heart and occasional tetanus of the uterus led to its disuse.

Quinine also had a vogue and was warmly recommended. Then followed a period of neglect and a recent period of revival of its use. Experimentally its effect in toning up the uterus is evident. But while it has this use clinically also, and is quite safe for the mother and child, its effect is inconstant, may not appear at all, may appear late or may be very slight. It is most effective in the period of dilatation. Very recently it has been used after pituitrin in cases in which the desired effect did not appear, and it has given gratifying results.

In considering ergot and its preparations and derivatives, we come at once to a field of active controversy. It is not because of any doubt as to the intensifying effect of ergot on the uterine contractions. This was known to Hippocrates. The drug is mentioned in the early Chinese literature and in the Middle Ages was much used as an abortifacient. Its use was known to be associated with danger and there occurred isolated cases of poisoning as well as epidemics of ergotism, the so-called sacred fire.

For over a century efforts have been made to obtain from the crude drugs the active principle in a pure state, and the effort, continued to the present time with the resources of modern chemistry, has not been crowned with unqualified success. Various substances have been isolated, one of which produces effects closely resembling the typical effects of ergot; the second is much like adrenalin, and a third is like preparations

of the pituitary gland. Still other substances have been obtained by other investigators. While this is very interesting from the theoretical point of view it has not much practical bearing, though very recently preparations have been produced which at first sight seem promising. As yet there has not been opportunity for their thorough trial.

The old question of when to use ergot, closed as some of us thought, has been opened again by Kehrer who found that in a series of closely watched cases, ergot at the end of the stage of dilatation had no tendency to cause tetanus. This differs from the generally accepted view and so the controversy has begun again.

Ergot is acknowledged to be the sovereign remedy for relaxation of the uterus following the expulsion of the placenta, but likely to cause some embarrassment if used during the third stage of labor. With reference to the use of ergot early in labor, Schatz, by means of the tokodynamometer, showed that small doses of ergot would increase the force of the uterine pains, without tetanus. But he also called attention to the difficulty of getting the exact dose required. Others tried fractional doses and claimed excellent results, but the weight of opinion has been, and still is, to wait until the end of the third stage.

It would seem that these difficulties are not inherent in ergot itself, but in the preparations of ergot, which deteriorate rapidly. The crude drug itself varies greatly in value according to conditions of growth which vary from season to season, and from district to district in which the ergot grows. These facts shift the problem to the pharmacologist or to the chemist, at least from the clinician for the present.

In view of all these facts, it is not to be wondered at that Hofbauer's communication in 1911, in regard to extracts from the hypophysis, was received with great interest. In 1885, Pierre Marie had first called attention to a relation between the genitalia and the hypophysis, in noting that there was some connection between acromegaly and tumors of the hypophysis. The etiological significance has been made clearer by surgery, in that removal of the tumor relieves and sometimes cures the symptoms. The description of Froehlich in 1901 of the clinical picture known as dystrophia adiposogenitalis showed that there were metabolic relations between hypophysis and sexual organs. Among other signs there is defective development of the secondary sexual characteristics. In the female, the hypophysis increases in size, during pregnancy, with fairly characteristic changes which regress after labor, but never entirely disappear. Increase in size of the hypophysis is found also following castration and in the senium, according to some investigators.

The effect of the secretion of the gland on the uterus was first determined by laboratory experiments in 1909 by Kehrer and by Dale. Clinical possibilities were at once recognized,

and it was soon used to control post partum hemorrhage and as a prophylactic in Cesarean section. Two years later Hofbauer used the extract to stimulate and strengthen labor pains, since which time it has been widely employed for this purpose. Factors which have favored its free adoption are its relative constancy, permanency and uniformity of composition, in marked contrast with ergot.

The results are not uniform, but certain facts seem to be pretty well established. For example, the dose is about one-tenth of a gram of the gland substance, corresponding to one cubic centimeter of pituitrin, but varying somewhat with preparations of other manufacturers. Increasing the dose above this quantity does not seem to increase the action and such variations in result as appear seem to be due to variations in the susceptibility of the patients. For if the contents of a one cubic centimeter ampoule be divided equally between two patients, there may be a marked effect in one and no effect in the other.

It may be given subcutaneously, intramuscularly or intravenously. While there is little difference between the subcutaneous and the intramuscular injection, the latter method is generally preferred. It should be given intravenously only in an emergency to check post partum hemorrhage, for its action is not only almost immediate, but stormy and accompanied by unpleasant but not serious general symptoms. By mouth it has no effect. After intramuscular injection the action is evident in from five to fifteen minutes, though sometimes later; if there is no reaction from the first dose in half an hour, a second may be given. But if no reaction follows the second dose, the patient is considered refractory and no further injection should be made.

The effect on the uterus during labor is peculiar and characteristic, producing a type of pains which closely resemble the normal. There is an increase in the uterine tone, with an increase in the force of the contractions, and a shortening of the duration of the contraction as well as of the interval between the pains. The shortening of the interval is most marked at first when the pains may occur in such quick succession as to give rise to a tetanic contraction of several minutes' duration. But generally no tetanus results, the interval, though short, being clearly defined. The effect lasts for about an hour, with its acme in the first half hour, and is generally not followed by a period of noticeable relaxation. It seems more active the nearer the patient is to physiological term, and if in labor the nearer the patient is to the end of labor. But in inducing labor it is of no value.

In regard to its use after the birth of the child there is wide difference of opinion, indicating that more study and observation are necessary to clear up this aspect of the question. Its injection has been recommended at the mo-

ment of birth to diminish normal bleeding and is undoubtedly valuable for intravenous use in post partum hemorrhage, where it acts promptly and uniformly. Thus it removes the need for intrauterine manipulation and to that extent diminishes the danger of infection.

Certain reports on the use of pituitrin would lead us to think of it as almost a panacea, with no failures, no bad effects and no contraindications. But a more thoughtful study of cases and a review of the literature show that it sometimes fails and sometimes does serious harm.

The failures ought to be studied with great care. They may be divided into two groups: first, those in which there was no uterine reaction—found chiefly in elderly primiparae and in women with undeveloped uteri; second, those in which the reaction was not of sufficient force to produce the expulsion of the child. It is this second group that especially demands attention, for here are the cases in which the misuse has been most obvious.

The bad effects outside the uterus are occasional, but never serious, at least as hitherto reported, and consist of pallor, faintness, cyanosis and irregularity of the pulse. The serious bad effects are in causing tetanus of the uterus which had led to asphyxia of the child and occasionally to rupture of the uterus.

The indications for the use of pituitrin may be summarized briefly. But before it is administered a careful examination should be made to determine whether the child can be born through the birth canal. The cases of rupture of the uterus have come chiefly from the neglect of this precaution. If it seems probable that the child can be so born, pituitrin may be given, first, for uterine inertia in the first or second stage. It has been recommended for both primary and secondary inertia, but I am inclined to be very cautious in its use before the cervix is dilated two and one-half inches.

The second group of cases comprises several subdivisions: those cases in which labor pains are normal, but for some definite cause increased activity is needed, as in a breech and occasionally in a face presentation; if the disproportion between the presenting part and the pelvis is slight; to avoid exhaustion of the mother from undue prolongation of labor; in eclampsia in connection with dilating bag. The only indication that needs comment is the use in eclampsia. Some have feared the dangerous effect of the rise in blood pressure, but this is not great, and I think we have a choice of evils, of which I consider the rise of blood pressure less than the prolongation of labor. It may also be used as a prophylactic against bleeding in Cesarean section.

A word should be said about adrenalin in this connection. Its effect in producing uterine contractions was noticed in 1901, but the study was not prosecuted with much vigor at first, and later interest was distracted by pituitrin. But it is the most powerful and promptly acting

oxytocic that we have, causing contractions in dilution of one to two hundred millions, and producing a powerful effect in dilution of one to fifty million. It is contraindicated during labor because it produces tetanus, but for post partum hemorrhage it is prompt and efficacious though temporary in its effect. It is best injected into the uterine muscle, as intravenously it is dangerous and subcutaneously not very effective. Ten minims of the one to one thousand solution may be injected into the wall of the uterus as high as may be reached on pulling down the cervix.

### A STUDY OF THE SYMPTOMS AND TREATMENT OF CONGENITAL TRANSDUODENAL BANDS.

BY JOHN HOMANS, M.D., BOSTON,

*Surgeon to the Peter Bent Brigham Hospital.*

THE investigation, of which the results are here presented, has been undertaken to throw light upon the question whether transduodenal bands of congenital origin give rise to such symptoms as to cause them to be considered a pathologic entity, having a definite course, symptomatology, and treatment.

The most convincing exposition upon this subject was made several years ago by Dr. M. L. Harris.\* Following the teaching of various anatomists, he holds the bands to be remnants of the original anterior mesentery of the upper gut, which, persisting after rotation of the stomach and duodenum in foetal life, remain stretched from the gall bladder and inferior surface of the liver across the duodenum to the region of the hepatic flexure. In general, the cases described by Harris run a long course, their symptoms resemble in certain respects both those of gastric and duodenal ulcer as well as chronic gall-bladder disease, and the Roentgen examination gives evidence of dilatation of the first portion of the duodenum.

Having met with a number of instances of these bands or adhesions, it has seemed to me worth while to make a study of all such cases occurring over a period of several years at the Peter Bent Brigham Hospital. There are now available eleven cases in which definite bands passing from the gall bladder and liver across the duodenum have been found, and in which gastric or duodenal ulcers or gall-bladder disease have been held to be absent. The symptoms of these cases have been tabulated for comparison with a series of six duodenal ulcers

and six gastric ulcers, picked out at random, one combined gastric and duodenal ulcer, eight cases of chronic cholecystitis with and without stones, and two cases of chronic appendicitis with reflex gastric symptoms. The late results in all patients whose bands have been divided are of course known.

The lesion, as I have met it, can best be described by quoting from one or two operative records and by reproducing a sketch made at operation. The first: (Surg. No. 3934, J. McG., Case IX.)

"There were a number of adhesions, apparently of a congenital type, passing between the lower part of the gall bladder and the cystic duct across the duodenum to the region of the head of the pancreas. These did not appear to indent or constrict the duodenum. . . . There was another band of adhesions, narrow and rather tight, which passed from a point just proximal to the pylorus to the liver itself rather high up beneath the inner part of the right lobe mesial to the gall bladder. These adhesions made a slight constriction in the upper part of the duodenum at about the point indicated in the x-ray as the seat of ulcer. After dividing these adhesions it was possible to feel exactly the whole duodenum and pyloric region and no induration or deformity could be made out."

Or again (Surg. No. 4247, D.T., Case XI, Fig. ure I.)

FIG. 1. Duodenum, Case XI, D. T. (Surg. No. 4247). The same patient as in Case IX. The band of adhesion is shown by a dashed line. The band of adhesion is shown by a dashed line. A searchlight is shown in the upper part of the picture.

"At a point just below the pylorus a very broad band of what appeared to be congenital adhesions attached the gall bladder, from a point beginning at the cystic duct downward for perhaps an inch and

a half toward the fundus, to the hepatic flexure of the large intestine and to the inferior surface of the pylorus just above this point."

Or again: (Surg. No. 1759, M.A.S., Case III.)

"Extending from the region of the head of the pancreas to the lower border of the pylorus was a small scar-like band. Where this band came to the pylorus there was a larger and more stellate scar, which, however, was not in the stomach wall but in the peritoneum with fat under it, evidently not the result of an ulcer, but an old congenital band. From this scar ran a much stronger, rather funnel shaped band across the junction of the first and second portion of the duodenum to the neck of the gall bladder where it finally spread out over half the surface of the gall bladder. This band made a pronounced indentation in the duodenum, evidently causing a kink if not an absolute obstruction."

These bands as described have a strong family resemblance to those congenital remains not uncommonly found at autopsy in infants and others. The frequency with which they appear at autopsy is uncertain, but I am very kindly permitted by Dr. S. C. Harvey to quote from a paper as yet unpublished to the effect that among 105 infants a condition of this sort was found by him 20 times.<sup>†</sup> It is not pretended that these bands are pathologic or, indeed, that they necessarily give rise to any symptoms. Holding such bands to be the object of this investigation, and excluding simple exaggerations of duodenal fixation as well as adhesions obviously resulting from ulcer or cholecystitis, I have analyzed the symptoms of eleven cases which presented this condition at operation.

*Age and Sex.* There were six males and five females, the average age of both being forty-four years, the youngest nineteen and the eldest sixty-seven.

*Duration of Symptoms.* The average duration of symptoms was eight to nine years. Two patients had suffered with gastric disturbances for twenty years and one for only four weeks. Curiously enough the latter was the oldest in the series, sixty-seven. She had had pneumonia severely some months before and had been left with a weak, irregular heart. She failed rapidly after her gastric symptoms appeared and was thought to have cancer. A novocaine exploration revealed a transduodenal band constricting the duodenum. The band was divided, affording considerable relief from her digestive disturbances, but her general condition continued to decline and she died a month after leaving the hospital, of unknown cause (cardiac probably). The death of this patient before any

definite proof could be offered that division of the band had proved curative makes it doubtful whether the anatomic lesion was in reality responsible for the gastric symptoms. The x-ray studies before operation disclosed an atonic, dilated stomach and no irregularities in the outline of the pylorus and duodenum. If, then, the band was of any importance symptomatically it could only have affected the stomach in a reflex way in connection with the sudden enfeeblement of the patient from other causes.

*Character of Symptoms.* The gastric disturbances have been analyzed under the convenient headings of intermittency, food relief, vomiting and bleeding, but their general character as well may be compared with that of other lesions. The complaints include "sour stomach," epigastric discomfort, fulness and gaseous eructations, a dull ache in the epigastrium with exacerbations, and dull, aching pain in right side of the epigastrium with knife-like exacerbations. In general there has been no radiation. There has been night pain in some instances, and sometimes pain before breakfast. Comparing these complaints with those of duodenal ulcer, it appears that in many instances the complaint is similar to the familiar, dull, distressing ache and gnawing discomfort of the latter, but that the patients suffering from trans-duodenal bands have a greater variety of symptoms. In this respect they present more the picture of gastric ulcer, and again the irregular time of appearance of the pain or discomfort is more like that of gall stones, though with the latter a large proportion of cases have, beside their "indigestion," a history of characteristic radiating gall-bladder colic.

*Intermittency.* Out of eleven cases, five had some intermissions in the steady development of their symptoms. These were irregular and not at all noteworthy, only one case having a resemblance to the typical course of duodenal or gastric ulcer. In general, the patient's discomforts were steadily present, much more so than among the gall-bladder cases among whom four out of seven had had irregular intervals of freedom, and in marked contrast with the gastric ulcer group, in all but one of which, an acute case of one month's duration, periods of complete relief were marked, and to those suffering from duodenal ulcer, among whom typical remissions were the rule. In this respect the symptoms of trans-duodenal bands resembled exactly those due to chronic appendicitis as studied in only two well-marked cases. It appears, then, that in respect to remissions, the bands are responsible for symptoms resembling in their lack of periodicity those due to reflex causes.

*Food Relief.* In six of the eleven cases food relief was noticeable and when present was of fairly long duration. That is to say, it more resembled that of pyloric or duodenal ulcer than that of ulcer of the lesser curvature. In the other five cases in which it was absent, the dis-

<sup>†</sup>For reference to this and allied conditions, together with a presentation of the literature upon these congenital folds, the reader is referred to Dr. Harris's paper and to that of Dr. Harvey, presently to be published, entitled "Congenital Variations in the Peritoneal Relations of the Ascending Colon, Caecum, Appendix and Terminal Ileum."

comforts had no relation to the taking of food or were immediately excited by it. In the latter respect the band cases resembled the instances of chronic appendicitis with reflex gastric disturbances. When the pain or distress bore no relation to the taking of food there was a closer resemblance to the indigestion of gall-bladder disease. There was, then, evidence in regard to the relief afforded by eating, that this symptom was less common than in gastric or duodenal ulcer and much more common than in gall bladder or appendicular disease. When, however, food relief was present, it tended to resemble that of pyloric or duodenal ulcer.

**Vomiting.** This symptom is so erratic in its appearance in ulcer cases that a comparison of these small series is hardly of any value, yet it may be significant that in the band cases it was present six out of eleven times, in duodenal ulcer not at all in six cases, in gastric ulcer five times out of six, and in gall-bladder disease four out of seven times. The symptom of vomiting, therefore, brings out again a similarity to gastric ulcer or gall-bladder disease.

**Bleeding.** No history of hematemesis was obtained from the patients suffering from bands, blood was never found in the stomach washings, and in only one case was there a story of bloody or tarry stools. The history in this instance was considered unreliable as the patient had previously been told she had an ulcer and was inclined to make the most of her symptoms. If there had indeed been haemorrhage, the source was not found at operation, but on the other hand a very deforming trans-duodenal band (the most completely so in the series). This absence of bleeding is to be compared with the conditions in gall-bladder disease in which a history of tarry stools was noted in one instance, in gastric ulcer, with which it was noted five times out of seven, and in duodenal ulcer, with which it was noted twice out of six.

**Gastric Analysis.** The familiar measurement of the free hydrochloric and total acids in the gastric contents proved to be of no diagnostic value in this series. In some instances the acidity was low or normal, in two instances free hydrochloric acid was absent, in another it was high at one time and absent at another, and in several cases there was present a continuous secretion of free hydrochloric acid for a number of hours after the test meal.

**Röntgen Examinations.** Studies in gastric and duodenal motility and in the position and outline of the stomach and duodenum showed abnormalities in all instances of well developed trans-duodenal bands in which this examination was made. Of the eleven cases, however, nine only were studied, and of these, one, the woman of sixty-seven already noted as of doubtful importance, presented merely a low atonic stomach. The findings in the other eight may, however, be used as a basis for study. There were three instances of duodenal defects, two of dilations of the upper duodenum, one of hour-

glass stomach, one of normal duodenum with gastric hyperperistalsis and one of normal duodenum with atonic stomach. As a rule bismuth passed through the duodenum so rapidly as to make a record of duodenal irregularities difficult to obtain, but the pylorus was generally regular in outline.

The Röntgen findings are, therefore, much more like those of duodenal than gastric ulcer, the one exception being the instance of gastrospasm, which of course is more common as an accompaniment of the latter than the former. But even here the spasm was so variable that, not being accompanied by any typical ulcer defect, it was correctly attributed before operation to reflex causes outside the stomach.

**Diagnosis.** Before describing very briefly the individual cases, it may be interesting to assemble the pre-operative diagnoses which were as follows: (1) "Cholecystitis with adhesions," (2) "Cancer," (3) "Gall stones or gastric ulcer," (4) "Cholecystitis or duodenal band," (5) "Duodenal ulcer or appendix," (6) "Duodenal ulcer or band, plus cancer somewhere in abdomen," (7) "Chronic appendix, ulcer or constipation," (8) "Pyloric ulcer, question of cancer," (9) "Duodenal ulcer," (10) "Gall stones," (11) "Duodenal ulcer, question of duodenal band." This list makes a poor showing in respect to the accuracy of diagnosis in the presence of this condition. It may perhaps be summarized more intelligibly.

A diagnosis of duodenal ulcer was made four times and was twice bracketed with band.

A diagnosis of gall stones or cholecystitis was made four times; was bracketed with gastric ulcer once, with band once, with "adhesions" once.

A diagnosis of cancer was made once.

A diagnosis of gastric or pyloric ulcer was made once and cancer bracketed with it.

A diagnosis of chronic appendicitis, ulcer or constipation was made once.

This variety in diagnosis is to be contrasted with the six analyzed cases of duodenal ulcer in all of which a pre-operative diagnosis of duodenal or pyloric ulcer was made, and with the gastric ulcers, in all of which a correct diagnosis of gastric ulcer was made. As for the gall-stone cases, the correct diagnosis was made in all the eight cases picked out at random.

It appears, therefore, that cholecystitis, duodenal and gastric ulcers are not likely to be mistaken for bands, but that bands may simulate the appearances of these other lesions, especially duodenal ulcer and cholecystitis.

Finally, and in the light of these attempts at diagnosis, a reanalysis of the various symptoms shows that:

The general character of the patient's complaint tends to resemble that of ulcer or gall-bladder disease, but gives the impression of a reflex symptom complex.

In respect to intermittency, the symptoms re-

semble gall stones or chronic appendicitis rather than ulcer.

In respect to food relief, the symptoms resemble those of gall stones and chronic appendicitis rather than gastric or duodenal ulcer, but when food relief is present it simulates duodenal or pyloric ulcer in type.

In respect to vomiting the disease is rather like gastric ulcer or gall stones.

In respect to bleeding, band cases present negative findings.

In Roentgen ray studies the band cases tend strongly to imitate duodenal ulcer.

#### PROTOCOLS.

CASE I. J. McD. 565. November, 1913. A nervous, apparently hysterical woman of 38. Indigestion for nine years, constipation. Attacks of pain and distress suggestive of gastric spasm for two years. Recent loss of fifteen pounds in weight. Intermittency (of indigestion), none. Food relief, none. Vomiting, present. Bleeding, none. Chemical examination, normal. Roentgen examination, long, hook-shaped stomach, slight atony, normal pylorus and duodenum. Pre-operative diagnosis, "Cholecystitis with Adhesions." Operative findings, a normal stomach, tight pylorus, duodenum in general rather thick and firm, adhesions across duodenum to head of pancreas. Operative treatment, division of adhesions, pyloroplasty (Finney) during which, mucous membrane of duodenum was found to be normal. Result, immediate, incomplete relief. After several months, complete relief, good gain in weight. At present well.

CASE II. S. M. A. 1458. July, 1914. A worn-out woman who had never fully recovered from a recent pneumonia. Age 67. For four weeks constant pain in pubic region radiating to epigastrium, back, and both sides. Good appetite, constipation. Marked loss of weight. Intermittency, none. Food relief, none. Vomiting, none. Bleeding, none. Chemical, free hydrochloric acid absent. Roentgen examination: low, dilated atonic stomach, regular pylorus and duodenum. Pre-operative diagnosis: cancer, location undetermined. Operative findings (novocaine exploration), general visceroprosis. First portion of duodenum dilated. Band containing fat and blood vessels passing from gall bladder to hepatic flexure and lower border of pylorus constricted duodenum. Operative treatment, band divided. Result: improvement in digestion, increasing cardiac irregularity, high blood pressure and general debility. Death soon after leaving hospital (exact cause unknown).

CASE III. M. A. S. 1759. September, 1914. An apparently neuritic woman of 41. For six years steadily increasing distress coming on 1½ to 2½ hours after eating. Recently constant "burning" in epigastrium and dull aching pain. Frequent attacks of "faint feeling" with hunger in epigastrium. No loss of weight. Intermittency, none. Food relief, present in early stages, less now than formerly. Vomiting, present, not of food eaten. Bleeding, questionable. (Patient claims to have noticed bleeding since hearing that she had a gastric ulcer). Chemical, only a few drops of strongly acid fluid recovered. Roentgen examination: hypertonic stomach, deep peristalsis, pylorus and duo-

denum defined and regular. Pre-operative diagnosis, "Gall Stones or Gastric Ulcer." Operative findings, normal gall bladder and stomach, a broad band containing fat and blood vessels passes from gall bladder (indenting duodenum) to inferior border of pylorus and on from there to head of pancreas. No evidence of duodenal ulcer. Operative treatment, excision of band. Result, for a few days no relief. From then on while in hospital complete relief. Was operated upon a year later at another institution (appendix, haemorrhoids). June, 1916. States that her indigestion and attacks of "faint feeling" in epigastrium were relieved by the first operation. Confesses to a fondness for pastry, etc., and says that if she eats sensibly she has very little trouble. Looks well.

CASE IV. M. A. O'K. 2715. April, 1915. A normal appearing girl of 19. For four years "sour stomach" at times. For three months, dull ache in epigastrium with exacerbations. Intermittency, at first present, later absent. Food relief, none. Vomiting, occasional. Bleeding, none. Chemical: fractional meal, first hour normal HCl, second hour diminishing HCl. Roentgen examination: hour-glass stomach, deep peristalsis, normal pylorus and duodenum. Pre-operative diagnosis, "Cholecystitis or Duodenal Band." Operative findings, normal gall bladder and stomach, broad band passes from gall bladder across (but not indenting) duodenum to lower side of pylorus. Operative treatment, division of band and removal of atrophic appendix. Result, Stormy early convalescence, then complete relief while in hospital. Later, one or two milder attacks of epigastric pain (none for eight months) and now considers herself nearly but not quite well.

CASE V. H. C. H. 2803. April, 1915. A stout, pallid man of 41. For twenty years indigestion appearing one to two hours after eating, recently colicky pain at same interval and occasional fainting attacks. No loss of weight. Intermittency, present, as in duodenal ulcer. Food relief, present. Vomiting, occasional. Bleeding, none. Chemical, on several examinations, HCl increased or absent. Roentgen examination, gastric hyper-peristalsis, irregularity of first portion of duodenum (Figure II), giving impression of duodenal ulcer. Pre-operative diagnosis, "Duodenal Ulcer or Appendix." Operative findings, friable gastric wall with no evidence of ulcer, small tight pylorus, a stellate scar associated with vascular adhesion passing from lower surface of liver across duodenum which was firmly fixed to liver. No induration of duodenal wall. Scar thought to be an old ulcer. Operative treatment, gastroenterostomy with plastic on antrum for purpose of exclusion. Result, Death from bronchopneumonia. Autopsy, no evidence of duodenal ulcer even on careful microscopic section of duodenal wall.

CASE VI. G. F. S. 3193. June, 1915. A man of 56. "Sour stomach" for 20 years. For last six years attacks of violent pain in early morning, starting at umbilicus and radiating to left, followed by dull grinding sensation. All symptoms worse recently, and has lost ground. Intermittency, none for indigestion. Food relief, present to some extent for many years but not recently. Vomiting, formerly some, recently none. Bleeding, absent. Chemical, hypersecretion of HCl, increasing in

FIG. 11. Case V, H. C. H. Duodenal defect thought to indicate ulcer. At operation a band was found. At autopsy, three days later, there was no evidence of ulcer.

second hour. Roentgen examination, prompt emptying, normal outline of stomach and duodenum, stasis in second portion of latter. Pre-operative diagnosis (a mass was felt in abdomen, hard and fixed to left of umbilicus) "chronic duodenal ulcer or band and cancer elsewhere in abdomen." Operative findings. Normal stomach, typical, fan-shaped band from gall bladder across duodenum to head of pancreas—duodenum compressed but not creased. Cancer of pancreas (inoperable, the growth occupied the tail of the pancreas to left of median line). Operative treatment, division of band. Result. Stormy early convalescence followed by relief for several weeks, after which his condition rapidly declined, his indigestion returned, and he died at home three months after operation. No autopsy.

CASE VII. M. A. McC. 3588. September, 1915. A neurotic appearing man of 30. For three months gastric discomfort immediately after meals, dull aching pain to right of umbilicus, with knife-like exacerbations beneath right costal margin. Intermittency, absent. Food relief, absent. Vomiting, present. Bleeding, absent. Chemical, continuous low acid secretion for several hours. Roentgen examination had been made in another institution and was not repeated. Pre-operative diagnosis: chronic appendix, gastric ulcer or constipation. Operative findings: normal stomach, light band from middle of gall bladder across duodenum, normal looking appendix. Operative treatment, division of band, appendicectomy. Result. For several weeks nervous and complaining, later gradual steady improvement in all respects with return to work and gain in weight, but still has to exercise care in eating.

CASE VIII. S.A.D. 3712. October, 1915. A stout, rather prematurely old appearing man of 50. For 18 years, discomfort and gaseous eructations

following three to four hours after meals. Formerly some epigastric pain in early morning. Constant hunger. Constant diarrhoea for 12 years. Recent loss of weight. Intermittency, absent. Food relief, present. Vomiting, absent. Bleeding, absent. Chemical, constant anaclidity. Roentgen examination, hyperperistalsis and much dilated pylorus and first portion of duodenum. Beyond this point duodenum emptied rapidly and could not be outlined. (Figure III). Pre-operative diagnosis, chronic ulcer with question of cancer. Operative findings, stomach normal, pylorus large. First portion of duodenum enormous. Broad band from gall bladder across duodenum to hepatic flexure compressing but not creasing duodenum. Operative treatment, division of band. Result, prompt improvement steadily continued for ten months (to date). Has to take HCl for his diarrhea. Gain above normal weight.

CASE IX. J. McG. November, 1915. An ignorant, rugged man of 42, somewhat alcoholic. Epigastric pain 3, 4 or 5 hours after eating, not coming after every meal, often at night, recently replaced by discomfort and "rumbling" of gas. Soda relief. Recent loss of weight. Intermittency, present, irregular intervals. Food relief, present. Vomiting, absent. Bleeding, absent. Chemical, hypersecretion, highly acid, continuing over several hours. Roentgen examination, normal stomach, no stasis, defect in anterior upper part of duodenum (Figure IV). Rapid passage of food through duodenum. Pre-operative diagnosis, duodenal ulcer. Operative findings, two distinct bands: the upper from lower surface of liver ducts, and above gall bladder across first portion of duodenum collecting into pylorus; the lower, from gall bladder and cystic duct across duodenum to head of pancreas not indenting duodenum. Normal stomach and appendix. Operative treatment, band excised. Result, immediate improvement but not complete relief. Roent-

FIG. III. Case VIII, S. A. D. Huge dilatation of duodenum associated with a band. First portion of duodenum larger than pyloric antrum.

gen examination three weeks after operation shows duodenum more deformed than before (Figure V). Steady gain under careful diet. Six months after operation, well.

CASE X. I. M. H. 3945. December, 1915. A stout woman of 53, self-indulgent in eating and careless in habits of eating. For three years epigastric pain "dull and aching," coming on sometimes early and sometimes late after eating. Recently night pain. Intermittency, none in sense of

periodicity, but relief in periods of careful diet. Food relief, absent. Vomiting, absent. Bleeding, absent. Chemical, not made. Roentgen examination, only for gall-stones, thought to be present. Pre-operative diagnosis, gall stones. Operative findings, normal gall bladder and stomach. A broad fan-shaped band passes from gall bladder across (not constricting) duodenum to lower side of pylorus. Normal appendix. Operative treatment, band divided. Result, no improvement for 10 days. Then steady improvement with relief of symptoms

FIG. IV. Case IX, J. McG. Before operation. Duodenal defect associated with deforming band.

FIG. V. Case IX, J. McT. After operation. Note increase in deformity following operation as compared with Fig. 4. The band has been excised.

except on indiscretions of diet to which she is subject. Gain in weight.

**CASE XI.** D. T. 4247, February, 1916. A rugged man of 49. For 10 years dull pain two to three hours after eating. These symptoms were ushered in by two severe attacks of epigastric pain following indiscretions of diet. Soda relief. Has since been on careful diet. Gradual loss of weight. Intermittency absent, but there have been a few free in-

tervals. Food relief, present. Vomiting, absent. Bleeding, absent. Chemical, fractional examination shows irregular secretion of acid, high at end of first hour. Roentgen examination, gastric hyperperistalsis. Rapid passage of food through first portion of duodenum, making outline difficult to obtain, but plates show defect in first portion. (Figure VI.) Pre-operative diagnosis, duodenal ulcer, question of band. Operative findings, normal stomach, pronounced band from liver and gall bladder cross-

FIG. VI. Case XI, D. T. 4247, February, 1916. With Fig. I, a sketch of the band, the patient opened and to explain the band.

ing and indenting first portion of duodenum to lower side of pylorus (Figure 1). On opening duodenum, mucous membrane and wall found to be normal. Appendix could not be seen. Operative treatment, division of bands, Finney pyloroplasty. Result, stormy convalescence with attacks of vomiting, followed by complete relief, ability to eat anything, and gain weight. Four months after operation, perfect health.

*Treatment.* At first sight the treatment of this condition may seem simple and yet I am inclined to think that division of the bands, or even excision and the inversion of surfaces bare of peritoneum, may not always prove satisfactory. In two instances I have opened the duodenum and performed a Finney pyloroplasty with more completely satisfying relief than in the majority of cases in which the bands were merely divided or extirpated. In the first instance (Case I), upon whom I operated before the publication of Harris's paper, the pylorus was so firm and tight as to appear pathological and demand examination of the mucous membrane. There was, however, upon splitting the pylorus, no evidence of ulcer past or present, and a plastic operation was done to obviate any possibility of subsequent narrowing. In the other (Case XI) the Roentgen plates showed such a definite duodenal defect that though I felt that the band which indented the first portion must alone be responsible, yet I thought it only fair to the patient to open the bowel. Both mucous membrane and duodenal wall were completely normal and a plastic closure with widening of the pylorus was demanded by the character of the incision.

There may, however, be a good reason for the excellent results in these two chance observations. Carman\* has recently pointed out that duodenal defects accompanying ulcers are quite possibly due to spasm of the duodenal wall, and an operation which sets at nought spasm, often perhaps of many years' standing, may reasonably be expected to be more effective than simple removal of the originally exciting cause of the spasm. This conclusion is quite tentative, however, and it must be admitted that division or excision of bands without the plastic is quite satisfactory.

Another observation (Case IX) casts still more light upon the relation of the duodenal defect seen in the Roentgen plates to transduodenal adhesions and their treatment. In this instance the pronounced defect seen in the plates (Figure IV) made a diagnosis of duodenal ulcer appear obvious and yet at operation only a deforming band was found. Under full anaesthesia, the duodenal wall was so normal in appearance and so free from any sign of ulcer on palpation that it was not considered necessary to open the duodenum. Accordingly the band was divided and nothing more was done. Three weeks after operation, however, bismuth studies

showed more deformity than ever, and in the language of the Roentgenologist, "the duodenum appeared as an irregular sinus." (Figure V). There can be no question, therefore, that spasm alone was responsible for the duodenal deformity, band being the apparent cause, and it was the persistence and even accentuation of the deformity that caused me to open and explore the duodenum in a subsequent case (Case XI) and to perform a Finney pyloroplasty. A comparison of the Roentgen plates in these two cases will show the obvious similarity between them (Figures IV and VI), and indeed, the symptoms in each were much alike. The results, however, though too recent to be considered final, speak in favor of the plastic operation, though the patient, who was subjected only to division of the band, has steadily improved under careful diet and bids fair to be well.

*Results.* All cases but one have been followed for periods of two and a half years in the first case to four months in the most recent. Of the eleven, two patients died of other diseases within a few weeks or months of operation. Both were improved but not completely relieved of their gastric symptoms. Another patient died of bronchopneumonia immediately after operation.

Of the eight living patients who have been traced to the present time, all are well or so nearly so as to express themselves as satisfied with their condition. Several still have to exercise care in their diet. Division of the bands may be said, then, to have been curative, with this reservation,—that division of the bands plus a plastic operation (Finney) has given more completely satisfying results.

*Relation of Transduodenal Bands to other Lesions.* A great many surgeons who have met these bands at operation have undoubtedly regarded them as a chance finding which, though unimportant, has saved them from the ignominy of a negative exploration. Moreover, owing to the very generally "reflex" character of the symptoms in such cases, operators are perhaps inclined, in addition to dividing the band, if indeed they consider this worth while, to remove a questionably abnormal appendix or gall bladder, and are thus at a loss to place exactly the credit for such subsequent improvement as their patient may make. For this failure the very ease and safety of much of the present-day abdominal surgery is responsible, but it is to be hoped that greater surgical self-restraint, together with a more perfect coöperation between patient and surgeon in the study of late results, may clear up this and many similar matters.

It is such a feeling which has led me to refrain from opening the duodenum in certain of the cases of this series, and I have carefully explained to such patients that their future health is, so to speak, "sub judice." By giving the treatment of these bands a fair chance, one

\* Carman, R. D.: Spasm of the Stomach and Duodenum from a Roentgenologic Point of View, *Jour. A. M. A.*, 1916, Vol. LXV, p. 1282.

may indeed be able not only to add to our understanding of their pathology but to make an important contribution to our knowledge of duodenal ulcer with which the Roentgen studies in this series show the bands may be confused. In this respect Carman's recent exposition upon the subject of duodenal spasm seems to me particularly important. If duodenal defects, as seen in Roentgen examinations, are always to be held as due solely to ulcer, then trans-duodenal bands may be of little importance and can be held responsible for symptoms only when they obstruct the bowel. In other words, the failure to find ulcer in instances of duodenal defects accompanied by bands is due to the operator and not to the absence of ulcer. On the other hand, if bands themselves, through spasm, can be held responsible for duodenal defects, it is probable that many diagnoses of "duodenal ulcer," when a band is present, are incorrect. The evidence adduced by Carman, that duodenal defects are very generally spasmodic constrictions excited by ulcer, seems to me worthy of acceptance and in that case it is not too unlikely that a condition such as transduodenal band may bring about a similar spasmodic deformity. In the small Brigham Hospital series three instances of typical deformities were noted in the Roentgen studies and attributed before operation to ulcer. No ulcers were discovered at operation in these cases, which have already been described in full (Case v, Figure II; Case ix, Figures IV and V; Case xi, Figure VI). They, therefore, support the contention that bands, in the absence of ulcer, may, by exciting spasm, be responsible for the defects, and they even suggest that in the presence of a trans-duodenal band a diagnosis of duodenal ulcer must be made only on strong evidence.

#### CONCLUSIONS.

1. Congenital trans-duodenal bands may be responsible for symptoms "reflex" in type, which have, in spite of considerable divergence, a definite family resemblance.

2. Accompanying these symptoms the Roentgen findings very generally indicate duodenal spasm or dilatation of the first, or first and second, portion of the duodenum.

3. Division of the bands and appropriate treatment of raw surfaces is satisfactorily curative, but plastic operations to widen the opening into the duodenum probably give the best results.

4. Congenital trans-duodenal bands, judging from the frequency with which they are reported at autopsy, are not necessarily pathologic, but may be responsible for digestive disturbances having a recognizable symptomatology, a prolonged course, and appropriate operative treatment.

## INDICATIONS FOR WET PACKS IN PSYCHIATRIC CASES; AN ANALYSIS OF ONE THOUSAND PACKS GIVEN AT THE PSYCHOPATHIC HOSPITAL, BOSTON, MASSACHUSETTS.\*

BY HERMAN M. ADLER, M.D., BOSTON.

HYDROTHERAPY has been in use in psychiatric hospitals for a long time, and all sorts of methods and theories have been employed with more or less success. Of late years, since the more modern ideas about hydrotherapy have gained the upper hand, elaborate provisions have been made in up-to-date hospitals for the application of Scotch douches, shower baths, needle baths, and so forth, whose effect has been reinforced by the use of steam baths, electric light baths, hot air, massage, and mechano-therapy.

The favorable experience of Kraepelin with the prolonged bath, which has been corroborated by numerous hospitals all over the world, served to establish this method as one of the necessities of a modern psychiatric clinic. Wherever the baths are consistently and intelligently given, strikingly good results have been observed.

Indications for giving baths have not, however, been very definitely set, so that the custom differs somewhat in the various hospitals where prolonged baths are given in the routine fashion. In general, the chief indication for giving a prolonged bath is restlessness. A patient becomes excited, noisy and violent, and is placed in a prolonged bath. Indications for the pack, on the whole, are the same as for the bath, except that the pack is especially indicated when the patient's ability to cooperate, or his suggestibility, is reduced to a negligible quantity. Mere excitement does not mean necessarily that hydrotherapy should be resorted to. It has been established that the chief signs are loss of body heat and loss of water.<sup>1</sup> These two apparently go hand in hand, and cyanosis of the exposed portions of the body, especially the face, hands and feet, is an index of the rapidity and the extent of the process. Hydrotherapy conserves the body temperature. It prevents the evaporation of water from the skin. It probably replaces some of the water lost, and it offers a gentle, mechanical restraint against sudden or violent gestures or motions.

The wet pack, as it is usually given, consists of a number of sheets wrung out in water at about 100 F., and wrapped tightly around the patient's body and limbs, so that he cannot move anything except his head, fingers, and toes—and an outside wrapping of blankets pinned with large safety pins, so that the patient cannot pull out of them. When the patient is so restless and active that in spite of

\* Being a B. S. thesis, it is published by permission of the Board of the Boston Medical and Surgical Journal. The previous author of this paper was Dr. M. A. Adler, M.D., of the Boston Psychopathic Hospital, Boston, Mass. It is published in the *Journal of the American Medical Association*, Vol. 10, No. 1, p. 10, 1917.

this, he is likely to fall out of bed in consequence of a flexion and extension of his entire body, a restraining sheet or blanket is placed over him and pinned to the sides of the bed, and the foot end of the pack may be attached by means of a blanket and safety pins to the cross bar at the foot of the bed. In this way, the patient is completely trussed and practically immobilized. In fact, this is so obvious, and the change from the violent agitation to the immobilization caused by the pack is so striking, that it must appear to many that the chief object of the pack is restraint, and is quite comparable to a strait-jacket or any other forms of restraint. As we shall see later, nothing can be further from the truth than this conception, and yet the similarity seems so great that even the attendants and nurses—not to say the physicians—frequently treat the pack as a form of restraint, and order it as a means of relief for themselves or the other patients from the disturbances caused by one who is merely noisy.

Where the degree of excitement is such that the gentle effects of the prolonged bath are not adequate, the restraining influence of the pack may be required to put the patient in the condition for the prolonged bath. The wet pack is applied for two hours. The patient is then removed whether he be still disturbed or not. If the patient has not fallen asleep or is not completely restored to quiet and self possession, he is then placed in the prolonged bath.

The ideal temperature for the prolonged bath is not over 98°F and not under 95°F. The water should be kept continually at this temperature, and the body should be immersed as far as possible in the water. The object of the pack is to produce an envelope of water or moisture-laden air at body temperature, and maintain this for the length of the pack. It has been shown that whether we start with cold water or warm water, the temperature of the pack readily adjusts itself to that of the body.<sup>2</sup> In cases of maniacal excitement, even though the patient may have fever, the surface of the body is losing large amounts of heat. It is wise, therefore, to start with hot sheets rather than cold sheets,—the idea being to conserve as much of the body heat as possible.

The patient should be given water to drink freely throughout the pack, and an ice-cap should be placed upon the head, and a cold compress on the forehead, which should be frequently renewed.

In cases of alcoholism or drug addiction, or in cases that have been exhausted by prolonged febrile diseases, there is a certain amount of danger from collapse in the pack. Following the experience in European clinics, as well as in this country, a hypodermic injection of digipuratum, or digitalin has been given almost as a routine in these cases. The ordinary preparations of digitalis such as the powdered leaves, the tincture or the extract, require sometimes as much as twelve hours before the effect is ob-

tained. They are, therefore, useless for this purpose. The hypodermic preparations are much more prompt in their action, and have given excellent results. Since the outbreak of the war, however, it has been impossible to obtain these drugs except at prohibitive prices, and stimulation with strychnin or camphor has been resorted to in cases in which there seemed to be a danger of cardiac collapse.

While the physicians who have been employing the pack in a proper fashion have all become convinced of the fact that it is a valuable therapeutic measure and in no sense to be compared to mere restraint, they have found this difficult to prove in individual cases; and in the face of charges brought by paranoid patients or their relatives, they have found it difficult to convince a prejudiced by-stander of the difference.

With these ideas in mind, a closer study was made of a thousand packs that had been given in the course of routine management of the patients at the Psychopathic Hospital, and the results of this study are herewith presented. These cases were gathered from unselected clinical material in the order in which they were given, and represent 309 patients. As will be seen from the table, the diagnoses, organic and psychiatric, comprise a large variety, and only one factor was taken into consideration in the present analysis, namely,—whether the patient was quieted by the pack or not.

According to this analysis, out of 309 cases, 155 were quieted by the packs, 56 were not quieted by the packs, 98 were quieted by some and not quieted by others, or, in other words, had a partial effect.

For the sake of convenience, I have grouped only the main classifications together. It will be seen that cases diagnosed manic depressive insanity and dementia praecox are very nearly equal in number—79 of the former, 82 of the latter. But 326 packs were given in the 79 cases of manic depressive insanity, with a quieting effect in 144, without quieting effect in 218 packs, whereas in the 82 dementia praecox cases, only 217 packs were given, with quieting effect in 143, and without quieting effect in only 74.

The same disproportion is shown by the cases of manic depressive insanity showing agitated depression. In 8 cases 26 packs were given, 8 with quieting effect, 18 without quieting effect. In all the other groups, including general paresis, delirium tremens, alcoholic hallucinosis, and epilepsy, by far the majority of packs had a quieting effect.

It would seem, then, that excitement in conditions other than manic depressive insanity is to be considered rather as a secondary manifestation, and one which is more easily controllable by hydrotherapy. Even in the cases of manic depressive insanity, of course, a quieting effect was obtained a large number of times, but the packs that were given without quieting effect outnumbered those that had a quieting

effect, indicating, thereby, also that the duration of the state of excitement and the intensity of the excitement are greater than in the other diseases.

These results are quite different from those obtained by the use of restraint without hydrotherapy. It is unnecessary here to recall the remarkable improvement in the condition of excited patients produced by the modern methods of non-restraint, in which diversion and occupation take the place of padded cells, strait-jackets, and strong rooms.

More to the point, perhaps, will be the startling figures obtained in a study of the treatment of delirium by hydrotherapy at the Psychopathic Hospital, Boston, compared to the results of the older methods of restraint and depressing drugs without hydrotherapy, employed at general hospitals. The mortality in general hospitals averages 26 per cent., the mortality in the Psychopathic Hospital, under hydrotherapy, more especially packs, averages 0 per cent.<sup>2</sup>

On account of these facts, it is safe to infer that hydrotherapy, whether applied in the form of prolonged baths or as wet packs, has a therapeutic effect, which is not to be obtained by mere immobilization of the patient or by restraint.

The question of restraint, of course, is an important one for administrative reasons. However, these figures prove that the wet packs not only cannot be condemned for reasons of cruelty, but that they are the most potent means of obtaining rest for a maniacal patient. The wet pack has been used at the Psychopathic Hospital consistently as an auxiliary to the prolonged bath, and bears the same relation to the latter that hypodermic medication bears to medication *per os*. A patient who cannot or will not swallow medicine may still derive the benefits from the drugs when they are administered subcutaneously. A subcutaneous injection of heart stimulant, for instance, may be applied against the wishes of an insane person. It may be applied in cases of unconsciousness and so forth. It offers a means of applying a therapeutic agent without the cooperation or even the consent of the patient. In the same way, the pack may be used to administer the beneficial effects of hydrotherapy, and in particular, of the prolonged bath, to patients who are so restless or excited that they cannot be induced to submit to the prolonged bath.

DIAGNOSIS	No. of Cases	No. of Packs	QUEDS FEDS	QUEDS FEDS

## JOHN CLARENCE CUTTER, M.D.

BY SARAH H. POWERS.

DR. JOHN CLARENCE CUTTER was born in Warren, Massachusetts, July 10, 1851, eldest son of Dr. Calvin Cutter, the author of Cutter's Physiology, and Ennie Powers, a woman of the old school of culture.

After he received his education in the public schools of Warren, he entered the Agricultural College at Amherst, from which he was graduated in 1872. He spent a year in J. B. Lippincott's publishing house, then attended Dartmouth Medical School for two years, from which he went to Harvard Medical School, where he was graduated in 1877. Before he received his diploma he had gained the post of house surgeon in the City Hospital.

In 1878 he went to Japan to accept the position of professor of physiology and comparative anatomy in the College of Agriculture, Sapporo, Island of Yezo. When he arrived at Tokio he was made the consulting physician of the Imperial Colonial Department. His first contract with the government was for two years. He was liked so well, that he renewed it from time to time until he had been with the college nine years. At his mother's urgent request, he did not renew his contract in 1887, but came home through Europe. Before leaving Japan, the Emperor conferred on him the Order of the Rising Sun, Meiji, fourth class.

While in Japan, Dr. Cutter wrote several physiologies which were translated into Japanese. After his return home, he revised his father's books, which had been translated into thirteen different languages and printed in raised letters for the blind.

In 1888 he went to Berlin and Vienna to study skin diseases. In the fall of 1890 he opened an office in Worcester. Soon after coming to Worcester, while assisting another physician in performing an operation, he contracted blood poison from which he never fully recovered.

Dr. Cutter came from a long line of famous ancestors on his mother's side, born in Warren. In Colonial times, they were foremost in the life of the town; they fought in the Indian Wars, in the Revolution, in the War of 1812 and the Civil War.

Dr. Cutter was energetic and possessed of forcible character. He had the courage of his convictions, and his fearlessness counted much

JOHN C. CUTTER, M.D.,  
Sapporo, Japan, 1884.

in accounting for the honors thrust upon him abroad."

One of his peculiarities was that he never turned the conversation on himself, so that very few knew the facts of his career. To a few intimate friends only would he allude to his travels or life in the Orient. After his mother's death in 1893, he gave up his practice and spent the following winter in Mexico and California. In fact (for the next three years) he traveled most of the time in the United States. He said he had been in every state and every territory but one in the Union. He was very fond of travel and said a train of cars had a peculiar fascination for him. In 1897 he received a shock, which left him with partial paralysis. It also affected his eyesight and memory. Several winters during his illness he spent with Dr. Robert I. Edes, in Boston. Although an invalid, he retained his interest in affairs of the world. He was particularly anxious to have us read to him the happenings in the medical world.

He did not remember what took place from day to day, but still could talk intelligently on most subjects. It seemed sad to see him, with a bright outlook and much good work planned, in such a condition, stricken in the prime of life. He was very patient, and never complained. When anyone alluded to his trouble, he would reply, "It is all right, it was to be. It had better be I than the other man, who has a wife and children. I have neither." He died February 2, 1909, of cerebral hemorrhage, after twelve years' illness.

He was straight and honest in all his dealings and wished others to be the same.

When his father died, he left debts to the amount of several thousands, all of which the doctor, with his mother's help, paid dollar for dollar, also the interest. When asked by one of his classmates why he did it, he replied, "I do not care to have people say, 'Oh! he got his education—and his father's debts not paid.' I'll have a clear conscience."

In his will he left the old home and land to the town of Warren for a children's playground, which was the first bequest of its kind, so far as is known, in this part of the country; to the Library Association, his books and some of the curios he had collected in the Orient, also his decoration from the Emperor of Japan, which he valued the most of all his many gifts that he received while professor in the Agricultural College at Sapporo, Japan.

His surgical instruments and his microscope were left to the City Hospital, Boston, Massachusetts. A sum of money, 1000 Japanese silver yens, equivalent to \$500, was given to the college at Sapporo, Japan, for a drinking fountain, suitably inscribed, to be placed on the college grounds; the income of \$1000 to the Agricultural College in Amherst, Massachusetts, to purchase books on hygiene.

To the Loyal Legion, Boston—curios of John Brown times.

After a few other bequests to relatives and friends, the residue of the estate was left to Harvard Medical School.

The remarkable scope of the testator's ideas is shown in the use assigned to the income of the property. It is a fund for maintaining a Cutter Lectureship on Preventive Medicine, one of the first bequests for such a purpose; these lectures to be free to all medical men, and to representatives of the press.

As specified in the will, the following inscription has been chiseled on the family monument in Pine Grove Cemetery, Warren, Massachusetts.

"JOHN CLARENCE CUTTER, B.Sc., M.D.  
Meiji IV Japan  
July 10, 1851  
February 2, 1909"

In closing this sketch of Dr. Cutter's life, there are two incidents which may reveal a little of his character.

As he was consulting physician and surgeon to the Imperial Government, he was not allowed to take fees, but could accept presents, and many of his rare curios were gifts from grateful patients. One of these is a rare specimen of ancient porcelain, which the owner, an old man, gave as the most valued of all his possessions. A bit of amusing history is connected with this gift. The old man had a young wife, who, as the doctor thought, preferred to have her spouse called to a higher life. The doctor set himself

to work to cure the old man who was so pleased that he gave him the ancient porcelain. While in Japan, the railroad from Otaru to Sapporo was built. Soon after it was completed, the doctor had occasion to take the train to go to a town, a short distance down the line. When out a few miles, the engine jumped the track. The Japanese did not know what to do. The doctor, who watched them in their efforts, finally asked for jack-screws and described them. They were found, and with his assistance, and directions to the Japanese, the engine was back on the track. They looked at him in amazement, and asked, "Do all the men in America know how to do everything?" He told them that most boys where he lived were taught many things, but not everything. The engine was very small compared with those in this country even at that time.

But the incident illustrates the resourcefulness of the man, which helped to win for him the admiration and confidence of those about him.

## Clinical Department.

### SYPHILIS OF THE LUNGS.\*

By NATHANIEL K. WOOD, M.D., BOSTON.

THE finding of extensive dullness of the lungs during routine examinations in cases that did not show tubercle bacilli in the sputum has interested me to collect data that would point to some other cause than tuberculous for such dullness.

At the same time the recognition of the Spirocheta pallida and the discovery of the Wassermann test have proved pathological findings, not heretofore recognized as such, a manifestation of syphilis. A striking example of what I mean is aortitis. Therefore, the question suggests itself, can the prevalence of lung dullness be correlated with the prevalence of syphilis? Can sufficient evidence be found clinically to justify a diagnosis of syphilis of the lungs? Is that evidence of sufficient weight to convince the pathologist that he is overlooking something, or calling something already seen by a wrong name?

From twenty-two cases, I have selected a series with histories suggestive of syphilis, whose physical examination showed definite lung impairment. If the Wassermann test proved positive, I had sputum examinations made and von Pirquet tests tried. If these proved negative, I had radiographs taken of the chest and long bones of the lower leg. I was able to select seven cases that showed definite histories, definite lung impairment, positive Wassermanns, negative sputum and von Pirquet tests. To these were added four cases which did not meet the

above requirements. One had a few tubercle bacilli in the sputum, Gaffky No. 2, but had in addition a markedly positive Wassermann test and definite radiographic findings. The three others were children, upon whom the diagnosis of tuberculosis had been made and who had been carefully treated for tuberculosis several years. Repeated examinations of their sputum have shown no tubercle bacilli, but their family histories were strongly suggestive of syphilis. No Wassermann tests or radiographs were made upon them, but I wish to cite them because of the marked effect which mixed treatment had upon them.

CASE 1. W. J., Male, January 29, 1915.

*F. H.* Could not be obtained.

*P. H.* Gonorrhea twice. Hard chancre.

*P. I.* Pains in abdomen. Cough and expectoration. Constipation.

*P. E.* W. d. & n. Skin negative. M.M. pale. Teeth bad. General glandular enlargement.

*Lungs.* Marked dullness in upper 2/3 and moderate dullness lower third, in front. Rare crackles left top. In back, few medium crackles above the spine scapula. Harsh respiration from the apex to the angle of scapula. Right back, diminished respiration upper half with few dry râles. Fairly good respiration lower half.

*Heart.* Not enlarged. Action regular. First sounds weak. No murmurs. P<sup>+</sup> plus.

*Liver.* Edge felt 1½ cm. below costal margin. Old scar of the penis.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Clavicles, lower ribs and tibiae show periostitis and endosteitis.

*Chest.* Aortitis. Infiltration lower third right lung.

*Weight.* 125 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

July 31, 1915. Has had a good month. No pain in abdomen for six weeks. No cough. Bowels move well. Eats and sleeps well.

*Weight.* 132½ pounds.

*Lungs.* Dullness in front remains the same. Respiration distinct. Fair excursion. Rare dry râles at apex left side. In back, dullness has decreased on the right side. Respiration is heard easily, excursion good, no râles. On left, broncho-vesicular upper half. Good lower half. Few dry râles, upper half.

February, 1916. Has improved since last note. Weight, 135.

CASE 2. C. M., female, 55 years old. Single. March 19, 1915.

*F. H.* Father and mother died when she was very young. Six brothers or sisters died before one year old.

*P. H.* Heart and kidney trouble 7 years.

*P. I.* Loss of appetite and strength, pains in joints, headaches, constipation, chronic cough with expectoration and shortness of breath. Poor memory.

*P. E.* W. D. p. c. n. Skin pale. M. M. pale. Teeth poor. General glandular enlargement. Chest small and flat. Clavicles and ribs prominent.

*Lungs.* Marked dullness both lungs throughout.

\* Read before the American Climatological and Therapeutic Association at Washington, D. C., May 31, 1916.

right more than left. Bases filled with moist râles. Musical râles the upper half. Respiration faint over upper half. Poor excursion throughout.

*Heart.* Right border 4 cm. to right of mid-sternal line. Left border, 13 cm. to left of mid-sternal line. Action very irregular, sounds faint, no murmurs.

*Liver.* Felt 2 cm. below costal margin. Oedema of ankles.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Both fibulae show periostitis. Chest, very large heart.

*Weight.* 157½ pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

March 25, 1915. Feels very much better. Very little cough. No oedema of ankles. Less headache.

*Lungs.* Few medium dry squeaks scattered over entire right and rare dry râles over left.

February 5, 1916. Slow and steady improvement. Looks and feels decidedly better.

*Weight.* 168. Memory improved.

*Lungs.* Few rare, sonorous râles in upper half of both fronts and over the entire back. Dulness the same.

*Heart.* Slightly irregular. A short presystolic murmur has developed.

CASE 3. W. P., male, 35 years old. Married. February 23, 1915.

*F. H.* Father died of tuberculosis. Mother alive and well. Two sisters died as babies. Four brothers and one sister alive and well.

*P. H.* "Brain fever" at age of 13. Rheumatism twice, last time 8 years ago. Several quinsy sore throats. Has two children, both poorly developed and poorly nourished. Has lost no children.

*P. I.* Ten weeks ago spat up one-half cup of blood. Blood streaked sputum for next three days. No more blood until three days ago. Since then blood streaked sputum. Cough for one month before first hemoptysis, then none until five days ago. Best previous weight 141, 16 years ago.

*P. E.* F. d. & p. n. Skin pale. M. M. pale. Teeth poor. Glandular enlargement marked. Chest narrow. Clavicles prominent.

*Lungs.* Marked dulness upper two-thirds of both lungs in front. Broncho-vesicular respiration right top. No râles in front. Marked dulness both backs throughout. Broncho-vesicular respiration upper half. Diminished respiration lower half. Few medium crackling râles left back from angle of scapula to base.

*Heart.* Right border right edge of sternum. Left border, nipple line.

*Liver.* Not felt.

*Sputum.* Negative.

*Von Pirquet.* Positive.

*Wassermann.* Plus plus.

*Radiographic Findings.* Clavicles, three lower ribs, tibiae show periostitis and endosteitis.

*Chest.* Infiltration both apices.

*Weight.* 127 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

March 6, 1915. Tubercle bacilli found in sputum. Gaffky No. 2.

*Weight.* 126½ pounds.

*Treatment.* Idem. Patient allowed to continue at work.

April 14, 1915. No tubercle bacilli found in sputum. Feeling very good. No blood streaked sputum since February 26, 1915. Coughs much less and raises only in the morning.

*Weight.* 132 pounds.

April 28, 1915. Feeling very well. Coughs rarely and only when he has to raise sputum. Raises less than one drachm in 24 hours.

*Weight.* 136½ pounds.

*Lungs.* Dulness upper half both lungs in front. Good respiration. Few to rare, fine and medium stretching sounds both bases. In back, dulness persists. Diminished respiration lower two-thirds on left. Rare medium, stretching sounds at base. On right, diminished respiration lower half, fairly deep respiration, rare stretching sounds scattered all over back.

*Sputum.* No tubercle bacilli found in sputum.

June 9, 1915. Says he feels as well as he ever did in his life. No cough, no expectoration.

*Lungs.* Respiration good. Excursion good. No râles heard.

*Weight.* 141 pounds.

August 3, 1915. Weight 143. Slight cough in the morning.

February 3, 1916. Has taken no medicine since August. Has felt well until the last few weeks. Now has choked up feeling in chest. Is coughing and raising.

*Weight.* 133 pounds.

*Lungs.* Marked diminution of dulness throughout both lungs. Front right apex rare fine crackle. Rare dry râles left apex. Good respiration. Good excursion. Back, diminished respiration left top. Rare, fine and medium stretching sounds upper half. Rare, fine and medium stretching sounds with cough to mid-scapula on right. Good respiration and good excursion entire right side.

*Treatment.* Resumed mixed treatment.

March 9, 1916. Weight, 136 pounds. Choked up feeling has disappeared. Cough and raises rarely.

CASE 4. M. C., female, 35 years old, married. March 10, 1915.

*F. H.* Father and mother living. Two brothers and five sisters living. Three brothers died in infancy before two years old.

*P. H.* Has had seven children. Three have died, one with diphtheria, two mal-nutrition, ages four and five months respectively.

*P. I.* Past four weeks headache and nausea. Poor appetite. Fatigue. Very constipated. Best weight 112, 15 years ago.

*P. E.* P. d. & n. pale. M. M. pale. Teeth bad. General glandular enlargement. Chest small. Clavicles prominent.

*Lungs.* Marked dulness throughout both chests. Faint respiration. Limited in excursion. Whispered voice plus over the right upper lobe. Rare, dry squeaks right mid back.

*Heart.* Right border mid-sternal line. Left border one finger breadth inside nipple line. Sounds weak at the base. No murmurs. P<sup>+</sup> plus.

*Liver.* Not felt.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Bones show nothing. Chest shows nothing.

*Weight.* 85 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

June 30, 1915. Weight, 88 pounds. General condition much improved. Pale and under weight.

*Lungs.* Dulness persists in lungs. Respiration fairly good in front. Diminished in back. Excursion good in front and fair in back. No râles.

March 14, 1915. From December 4, 1915, to January 27, 1916, was given injections succinamide of mercury, gr. one-fifth. Since then has felt very well.

*Weight.* 94 pounds.

*Lungs.* Continue to show dulness, but good respiration.

CASE 5. E. W., female, 36 years old, married. April 8, 1915.

*P. H.* Negative.

*P. H.* Asthma and bronchitis several years.

*P. I.* Cough all winter. Poor appetite. Loss of 10 pounds last few months.

*P. E.* F. D. f. n. M. M. male. No glandular enlargement. Chest barrel-shaped.

*Lungs.* Marked dulness throughout both, especially upper two-thirds. Harsh respiration throughout. Some to few, medium and coarse wheezing râles over entire chest, front more than back.

*Heart.* Cardiac area normal. No murmurs.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Bones show nothing. Chest shows nothing.

*Weight.* 107 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

July 30, 1915. Temp. 99.2. Weight, 112½ pounds. Feels very much better. No cough. Has raised nothing for eight weeks.

*Lungs.* Much less dulness. Right front few, fine and medium squeaking râles with cough, scattered over entire side. On left, rare, fine and medium, dry squeaks with cough scattered over upper half. In back, few fine, medium and coarse squeaking râles with cough scattered over both sides, top more than base.

September 2, 1915. Weight, 119½ pounds. Feels very well. No subjective symptoms referred to chest.

*Lungs.* Clear throughout.

CASE 6. G. A., male, 22 years old, single. Mar. 26, 1915.

*P. H.* Negative.

*P. H.* Severe pneumonia in childhood affecting left side. Gonorrhea and chancre.

*P. I.* Bad cough for two months. Feels weak. Has lost 10 pounds in two months. Occasional night sweat. Raises thick, yellow sputum.

*P. E.* W. D. & N. Good teeth. General glandular enlargement. Chest, good size.

*Lungs.* Very marked dulness over entire left side and marked dulness upper two-thirds of right. Moderate dulness lower third. Faint respiration over left side. Râles scattered throughout left.

*Heart.* Right border mid-sternal line. Left border not determined.

*Liver.* Edge felt. Is tender.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Plus plus.

*Radiographic Findings.* Periosteitis of bones suggested. Chronic pleuritis of left lung.

*Weight.* 122 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

May 25, 1916. Has improved but little. Feels weak and tired. Pain in the left axillary region.

*Lungs.* Dulness persists. Good respiration on right side. Few to rare, fine clicks scattered over lower half. Left front, bronchial respiration fourth space. Some to few, fine and medium, sticky râles or pleuritic rubs with cough. Left back, few, fine, medium sticky râles with cough to spine. Some fine, medium and coarse friction rubs from spine to angle. Few fine and medium, pleuritic rubs from angle to base.

April 13, 1916. Has taken treatment regularly. Wassermann test negative. Weight, 142 pounds. General condition excellent. No cough. No expectoration.

*Lungs.* Marked dulness persists over left. Some dulness on right. From above downward on left, few, some to considerable fine, medium and coarse friction rubs front and back. Few, fine friction rubs at base of the right.

CASE 7. C. S., female, 52 years old, married. October 1, 1914.

*P. H.* Husband died, shock, age of 63.

*P. H.* Has had six children. One died at three months, one at five months, one at one and one-half years old. The latter, however, of diphtheria. Dizziness and headaches occurred at three or four days' intervals for several years.

*P. I.* Increasing attacks of the above. Dizziness is more severe and lasts longer.

*P. E.* W. d. & f. n. Glandular enlargement. Poor teeth. Chest small. Clavicles prominent.

*Lungs.* Show slight dulness upper half and front and marked dulness from the spine to the angle of scapula both backs. Rare, dry râles left back.

*Heart.* Right border, right edge of the sternum. Left border, nipple line. Loud systolic murmur at apex transmitted to axilla.

*Liver.* Edge felt.

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Periosteitis and endosteitis of the tibia. Chest, aortitis.

*Weight.* 135 pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

June 21, 1915. Feels very much better. Very little headache. No dizziness. Sleeps well. Weight, 146½ pounds. Chest examination practically the same.

July 26, 1915. Has taken no medicine for four weeks. Feels well. Weight has dropped, however, to 140½ pounds.

*Lungs.* Clear throughout. Good respiration. Good excursion.

January 21, 1916. Has taken medicine irregularly. Feels rather poorly. Weight, 140 pounds.

May 1, 1916. Has taken medicine regularly last two months. Weight, 142½ pounds. Feels very much better. Lungs perfectly clear.

CASE 8. M. G., female, 37 years old, married. colored. April 22, 1915.

*P. H.* Negative.

*P. H.* Two children. Two gonorrheas.

*P. I.* Twelve years' pain in left lower quadrant. Worse on exertion and when constipated. Loss of 12 pounds in last five months. Slight cough and expectoration.

*P. E. W. D. & W. N.* Teeth bad. No glandular enlargement.

*Lungs.* Moderate dulness upper two-thirds of both. Good respiration. Good excursion. Few scattered râles right back.

*Heart.* Right border, right edge of sternum. Left border, nipple line. Systolic murmur over the right side of the heart at apex, not transmitted to axilla.

*Abdomen.* Tenderness lower left quadrant. Tube?

*Sputum.* Negative.

*Von Pirquet.* Negative.

*Wassermann.* Positive.

*Radiographic Findings.* Tibiae suggestive. Aorta suggestive. Heart very large.

*Weight.* 167½ pounds.

*Treatment.* Tr. nux and gentian before meals. Mercury and potassium iodide after meals.

May 27, 1915. Has had occasional night sweats. Does not cough. Raises nothing. Sleeps poorly. Lungs show good respiration. Good excursion. No râles.

July 24, 1915. Weight, 170 pounds. Feels much better. Says she has some pain in her chest, but says that her respiration is deeper than formerly.

*Lungs.* Rare stretching sounds over lower half of back.

February 24, 1916. Has done well all winter.

*Weight.* 174 pounds.

*Lungs.* Show good excursion, good respiration. Scattered stretching sounds.

CASE 9. L. A., boy, 10 years old. December, 1911.

*F. H.* Father and mother alive and well. Mother has had two miscarriages. Father, dissolute.

*P. H.* Age of 6 months was dropped. At age of 10 months developed abscess of the right hip, resulting in ankylosis of hip joint.

*P. I.* Very weak. Cough and expectoration. Discharging ear. Inflammation of the eyes. Poor appetite.

*P. E.* Has marked Hutchinsonian teeth, as have one brother and one sister. P. D., emaciated, very pale. Marked glandular enlargement.

*Lungs.* Marked dulness. Râles and poor respiration.

*Weight.* 46½ pounds, stripped.

June 12, 1913. For a year and a half has had careful anti-tuberculosis treatment. In that time he has gained 11 pounds. Physical signs have improved decidedly. Mixed treatment started on this date.

December 19, 1914. This last year and a half the patient has gained 15 pounds. The improvement has been very marked. Much less lung involvement.

*Sputum.* Repeated examinations of sputum have failed to find tubercle bacilli.

CASE 10. C. B., little girl, 11 years old. February, 1913.

*F. H.* Mother a drinking woman who was deserted by a drinking husband. Adopted at age of 6 months.

*P. H.* Constantly ill. Frequent colds. Digestive upsets. Never able to go to school. Eczema of nostrils, corners of mouth and back of ears.

*P. I.* Referred to me after one and one-half years of treatment for tuberculosis in a public institution.

*P. E.* Showed extensive involvement of the lungs and a poorly developed and emaciated child. A careful record of temperature showed daily temperatures of from 100 to 101.5 for a period of four months. Weight, 65½ pounds.

January 8, 1914. After 11 months' rigid anti-tuberculosis treatment. This child was still very weak, showed marked trouble of the lungs and weighed only 65¼ pounds. Mixed treatment started on this date.

January 7, 1916. Marked and rapid improvement during entire year. In October the child was able to go to school for the first time in her life and has missed only two days of school.

*Lungs.* Showed marked improvement.

*Weight.* 78½ pounds, a gain of 13¼ pounds.

*Sputum.* Repeated examinations of sputum have failed to find tubercle bacilli.

CASE 11. G. P., small boy, 9 years old. December 9, 1909.

*F. H.* One uncle and one brother epilepsy.

*P. E.* Marked Hutchinsonian teeth. Marked lung involvement.

June 19, 1913. After three and one-half years' treatment, this boy gained 20 pounds. Condition of lungs has shown no improvement during the past year. Mixed treatment started on this date.

October 4, 1915. Two and one-third years later this boy has gained 24½ pounds. The improvement of the lungs has been as marked as his improvement in general condition. No tubercle bacilli have ever been found in his sputum.

No Wassermann tests or x-ray examinations have ever been made on these last three cases.

#### DISCUSSION OF FINDINGS.

There is strong evidence of syphilis in these individuals; previous history of sickly children, born into families where there has been a series of miscarriages, dead-born children and early infant deaths; subsequent history of chancre, or loss at early age of their own children; physical signs of general glandular enlargement, Hutchinsonian or badly decayed teeth, sears and skin eruptions; positive Wassermann tests; radiographic findings very positive in three cases, suggestive in three others of syphilitic bone lesion and circulatory lesions. There is equally strong evidence of disease of the lung; marked dulness throughout both chests; poor respiration, limited excursion; varying numbers of moist and dry râles confined more to the bases than the apices of the lungs; history of cough and expectoration. The following evidences of disease were found by the radiograph: periostitis of the tibiae, fibulae, clavicles and ribs; marked broadening of the arch of the aorta; enlarged heart; infiltration of the lung tissue; pleuritic thickening. Definite involvement of bones, aorta and lungs was found in three cases; suggestive involvement of the bones was found in three others, one of the latter showing an enlarged heart and broadened aorta, another an enlarged heart and another pleuritic thickening.

These cases have been under treatment about one year. They have observed simple hygienic rules such as early hours, good food, three meals

a day, re-enforced by two luncheons. In addition they have had Tr. nux and gentian before meals and mixed treatment after meals. One had injections of mercury for five months. All but one has worked steadily. The results of treatment have been small gains in weight, 3 to 16 pounds, great improvement in general physical condition, marked diminution of tendency to take cold, and improvement in chest findings such as disappearance of râles, deeper and steadier respiration and diminishing of dulness. In the one case in which tubercle bacilli were found, no tubercle bacilli could be found subsequent to six weeks of mixed treatment. When this individual stopped mixed treatment, he gradually lost ground, which was regained at once upon the resumption of mixed treatment. Of the three children, one gained in the first  $1\frac{1}{2}$  years of treatment 11 pounds, then the only change in treatment was the addition of mercury and potassium iodide. In the next  $1\frac{1}{2}$  years he gained 15 pounds and the lungs showed a corresponding improvement. Another lost, after one year of treatment,  $\frac{1}{4}$  pound, then mercury and potassium iodide were started. At the end of nine months she had improved so much that she was able to go to school for the first time in her life, and when the year was completed she had gained 13 pounds in weight. The third was under treatment for three and a half years before mercury was given. During that period he gained slowly, the lung condition cleared up very slowly and his weight increased only 20 pounds. After the mercury was started, in  $1\frac{1}{4}$  years' less time he gained  $4\frac{1}{2}$  pounds more, or  $24\frac{1}{2}$  pounds. His lungs, which had shown no improvement for a year, showed marked diminution in dulness, marked increase in respiratory excursion and all râles disappeared. In addition to these marked gains in weight, these children have grown from three to five inches taller since the mercury was started.

#### EVIDENCE, IF ANY, OF SYPHILIS OF THE LUNGS.

We must first establish the fact that there has been disease of the lung in these cases. This is proved by the respiratory symptoms, such as cough and expectoration, tendency towards frequent colds, poorly developed chests, poor expansion, marked dulness and râles varying from few to some and from dry to moist. The radiographs show infiltration in two of the lungs and pleuritic thickening in another. These conditions occurred in individuals where the only signs pointing toward tuberculosis were the physical findings of the chest examination. Family exposure to tuberculosis is lacking, no tubercle bacilli were found in the sputum and von Pirquet tests were negative. On the other hand there is good evidence to point to syphilis in other parts of the bodies, at least of these people. The family and personal history conforms to that diagnosis, the physical examination is in favor of it, the Wassermann test is positive in

contrast to a negative von Pirquet. In three cases the long bones show definite syphilitic lesions and in three others suggestive lesions.

Finally, the evidence of treatment favors the diagnosis of syphilis. These patients were allowed to work, they did not attempt to live or sleep out of doors, but were given instead tonic treatment together with anti-syphilitic treatment. That they made definite improvement is very certain, that they retrograded when they stopped treatment is equally certain. In the cases of the three children, the improvement in condition, after long and most careful anti-tuberculosis treatment, was most marked, and can scarcely be called a coincidence or one that was bound to follow because the tuberculosis was being cured. This improvement was much the longest delayed in that case from which the mercurial treatment was withheld the longest. This improvement under mixed treatment has not taken place solely in the general condition. The local condition of the lungs has improved. Shortness of breath has diminished, asthmatic attacks have disappeared, tendency to take cold has ceased, respiration has become deeper, clearer, râles have dried up and finally the amount of dulness has lessened.

#### CONCLUSIONS.

We have, therefore, cases showing definite lung lesions in persons who lack two definite laboratory signs of tuberculosis, positive sputum and von Pirquet tests, and who give no history of contact with tuberculosis. These persons, on the other hand, react positively to the Wassermann test, have definite family history of syphilis, show syphilitic lesions elsewhere in the body, and respond rapidly to syphilitic treatment. Most important, the local condition of the lungs improves as definitely under syphilitic treatment as does the general condition.

To me, however, the evidence which I have tried to secure is far from conclusive. Too often tubercle bacilli cannot be demonstrated in the sputum of patients who have later been proved to have tuberculosis. The number of cases which I could collect have been too few, the difficulties of controlling them too great; and the lack of radiographic confirmation of demonstrable lesions in the lungs, themselves, leaves us with result of treatment as the strongest link in our chain. This is far too weak a link to overthrow the strong evidence of the pathologist that syphilis of the lungs is very rare.

I realize fully that if there is such a thing as syphilis of the lungs it must be demonstrated on the autopsy table. Of, however, the facts of medical treatment and clinical observation continue to point toward such an infection of the lungs, as I believe they will, greater efforts must be made to find pathological corroboration.

## CONTROL OF SCARLET FEVER.

BY D. M. LEWIS, M.D., NEW HAVEN, CONN.,

*Epidemiologist, Board of Health.*

FROM lack of epidemiological observations on sporadic or endemic cases, the control of this disease is as yet limited to the search for missed cases and the supervision of reported ones. I wish to show that it is possible to demonstrate the carriers of this disease, who, as responsible for the missed as well as the reported cases, are, consequently, the basis for the control of scarlet fever.

The following two cases are illustrative of the type of carriers which are now being recognized rather generally as those who give rise to recurrent cases.

CASE 1. Females, ages 2 and 3, sisters, were reported March 11, 1914. A third sister, age 14, was on that date sent from the house. The reported cases were ready for release and fumigation at the expiration of four weeks. The child aged 2 showed at this time an unfaded tongue, the so-called strawberry tongue, and an edematous, hyperemic throat as contrasted with the sister age 3, whose mucous membranes were quite normal. Though warned as to the danger of further contact with the first mentioned child, the family paid attention only to the fumigation of the entire house that the sister of 14 might be immediately returned to the home. One week later this sister in turn was a reported case. The younger sisters at this time showed the same signs as on their release one week previous. At the time of release of the last reported case, the mucous membranes of all three were normal. During and following this period there were no further neighborhood cases.

CASE 2. A male, age 14, was reported March 9, 1914. Released without inspection at the expiration of one month, the entire house was fumigated for safety for expected company. Within a week the visitor and a friend were both reported cases. The first case at this time showed the characteristic tongue, a markedly edematous throat and an acute rhinitis. With his isolation for some three weeks until the membranes were normal, there were no further cases until November of the same year when a chum of this case was reported with the disease. Again looked up, this boy was found to be again showing a very typical strawberry tongue and a subacute naso-pharyngitis. With his isolation for some two weeks when his membranes had become normal, there were no further cases in the neighborhood for the season.

The following case is similar to the preceding though given as illustrative of how the disease may start up in the fall.

CASE 3. Male, age 5, was reported November 2, 1914. Released at expiration of six weeks with discharging ears and purulent nasal discharge. During following two months there were four neighborhood cases in children of the same age. On August 2, 1915, while seeking diphtheria carriers among some nursery children at their shore cottage, I saw a

boy being admitted who had an ear filled with cotton, a purulent nasal discharge, a marked streptococcus sore throat, a strawberry tongue and a temperature of 102. I asked the matron of the institution to isolate this child until they could learn his home address as he was undoubtedly a case of scarlet fever. The following day I was informed that he was the child described as a case of November, 1914. Without ensuing rash or desquamation, it was only after six weeks' treatment that the nasal discharge was cured and the tongue faded. Through the entire season there has been no case of scarlet fever in this boy's neighborhood, nor has he again stirred up the naso-pharyngeal recurrence of the summer.

The following cases represent types of carriers not yet recognized either by health authorities or by physicians.

CASE 4. Three children, ages 7, 9, and 10, had scarlet fever in March, 1915. As absentees from school in mid November of that year, they were looked up and the following conditions were found. The youngest had had nasal hemorrhages and a purulent nasal discharge for the past four weeks. The other two had had sore throats. All three had characteristic strawberry tongues and inflamed pharynges. All had been treated for malaria and confined to the premises with one exception. The youngest child had played with a new arrival in the neighborhood on one occasion when he had been left alone. A week later this new arrival was a reported case of scarlet fever. This fact was learned at the time of release of the reported case. At the time of beginning quarantine, the mother had been certain that there had been no contact with any neighborhood children, even to her child never having been out of the yard. Later from a neighbor she had learned the fact mentioned.

CASE 5. A female, age 10, had had scarlet fever 4 years previously. A brother age 6, as a school absentee, on examination, showed a throat and tongue suspicious of a recent mild scarlet fever. Onset had been attended by vomiting and fever. The sister mentioned also showed the strawberry tongue and a subacute throat. An older sister who also had had scarlet fever four years previously, showed no signs. The present history was that first the girl, then the boy had been sick with malaria. My records showed that at this time I had two cases referable as to age, sex and school, with these two children, and reported some two weeks after their onset of "malaria." Both boys were in a neighboring school; both girls in a remote one. Both sets were playmates.

CASE 6. Male, age 7, had scarlet fever two years previously. Seen in November, 1915, as a school absentee, he presented, according to his physician, all the signs of scarlet fever except the rash. The onset was with vomiting and high temperature. Had he not attended the boy previously for scarlet fever, the physician stated that he would have at this time reported him as a case. Only after three weeks' isolation did the mucous membrane become normal.

CASE 7. A female, age 12, had had scarlet fever school absentee, this girl showed a recurrent otitis

media and a recent sore throat. The tongue was a fairly typical strawberry type. Out of school but not house confined, this case accounted for two cases of girl chums reported March 16, and an older brother reported on March 20. The records showed that she probably accounted for some six neighborhood cases in girls, two of whom were in another family in the house, during the preceding year at a time that we now learned that she had had a similar disturbance.

CASE 8. A female, age 20, was sent to the isolation hospital as a case of diphtheria. A culture sent me by the physician showed a pure streptococcus. The hospital stated that they would entertain my diagnosis of scarlet fever from the very characteristic tongue and throat. At the end of one week, failing to find any eruption or desquamation, and finding that the patient had had the disease 10 years previously, on her request she was discharged. Attempting to obtain the history of any infective periods during the ten year period, I found that a sore throat of the previous year corresponding to a period when scarlet fever was beginning to appear in a corset factory only to shift to a munition factory. The three cases in the first factory were in girls, those in the latter were among men. Some few days after her sore throat had commenced, this girl had left the corset factory and began work in the munition factory. A week later began a long series of cases among men in two different machine shops and a few of the central office force. At that time, I had found that the only common communication was through a force of girls who handed out and received back machine tools for these men from behind a counter. The central office force also had contact with these girls. Numbering upwards of 100, I had asked the factory sanitarian to examine this set of girls for strawberry tongues and red throats. The following day he reported that he had found none. I now had the data that she had been one of this set of girls. Further past history was refused when I pointedly asked as to the disease having been present in houses where she had lived, although a friend who was present remarked on the fact that once when she had had one of her sore throats, a girl in the house had later had scarlet fever. This case represents the longest time interval after having had the disease of showing the signs of a carrier that I have yet seen. The buccal-pharyngeal signs even after the now ten days' illness were the most marked that I have yet seen. The basis for this was apparently an extraordinary lymphoid hypertrophy of the naso-pharynx.

*Proving of carriers.* That those individuals who have at the end of convalescence ear or gland discharges, may be carriers needs at the present time no proof. That those who have had the disease previously may be carriers can be proven under the same conditions as the former. The one essential is that both groups shall show some grade of buccal-pharyngeal inflammation as shall be characteristic of primary scarlet fever. With the subsidence of this factor in the first group and its absence in the second group, I do not find individuals infective. That both groups are infective during its presence, is demonstrable by the recurrent cases in the family if the first group is then in contact with suscep-

tibles, and by the absence of further cases in the family or friends when the second group is isolated. With the finding of carriers of the second group when they are confined to bed, I have found that a single exposed individual in the family may develop the disease. Otherwise, and especially where there are no other children in the family, I have found that I have had neighborhoods where such individuals have been found in the early fall, isolated for the three and even longer weeks of the tongue and throat inflammation, and the entire season passed with no cases of the disease appearing. Again, where these individuals have been found after there has been one or more cases of generally, the same sex, age and factor of being playmates, there will be no further cases when that individual is isolated. In one instance where the individual could not be controlled there was a later case. A further factor of proof is that in doing neighborhood survey work, I have seen these carriers, previously showing positive signs and apparently accounting for reported cases, later have sore throats without positive signs, be permitted their freedom of contact and not have cases of scarlet fever follow.

*Results.* During the first four months of epidemiological work, the usual régime of quarantine and terminal fumigation then holding, I had 4 recurrent cases in a total of 198 cases. During the following two years with approximately 500 cases, I had but 1 recurrent case. That was an instance where from necessity the quarantine had to be removed and only the convalescent carrier isolated. Unknown to me, one of the children of the family who had been a hospital resident for four months was then returned to the home and in one week was a reported case. During the first year of simple isolation of the one sick with inspection to prevent convalescent carriers, doing away with fumigation, I prevented secondary as well as return cases. This in spite of the fact that less than 10% of the cases were hospitalized. During the second year with the added factor of finding of the carriers who had previously had the disease, I have had a lessened number of reported cases. Of yet greater importance is the result from the simplified procedure of quarantine based on my results in diphtheria, which disease has been made infrequent in incidence compared to all previous years and with reference to other cities of this state for this year. Based on the frequency with which I could demonstrate carriers who had had the disease either in the family, in other families in the house or neighborhood, the procedure is as follows: Immediately after inspection at the time of quarantine, all school children in the same house, but outside the family, are returned to school from that residence. All children in the family concerned are returned if they will live and board with another family in the house or neighborhood. Any carrier in the family, house or neighborhood, was isolated, though given rear yard freedom during school

hours, if under supervision, and there were no children to gain access to the yard. All adults were allowed to live at home irrespective of occupation. Inspection of adults was insisted on only when there was a history of previous sore throats or the adult was a raw food handler. Of upwards of one thousand children and one half that number of adults returned to school and work respectively, at the time of instituting quarantine, I have had but two instances of secondary cases in the family, house or neighborhood when the carrier was found. One was in a child who contracted the disease three weeks after she was returned to school from a remote neighborhood, the other was an adult who contracted it from his wife who in turn contracted it from taking charge of a case of the disease in the family. Otherwise, none of these individuals given their usual previous freedom of living have developed the disease. I have then the proof that the secondary cases so frequent previously were not due to being exposed by the one sick but by the carrier. In diphtheria, as well as scarlatina, it has been my experience that no matter how poor the isolation of the patient ill, irrespective of the ages of the other children in the family, none will get within reach of the one ill, all will flock on the other hand to the carrier. The latter's popularity may always be estimated by the number of cases he causes.

*Finding of carriers.* As described in my article on the Control of Diphtheria, postal card notification of all school absentees, as well as those who are in school and have nasal or ear discharge, is the basis for finding carriers. A Visible Index of all previous cases with their addresses is also made use of when no carrier can be found in the house of a reported case.

*Frequency of carriers.* During the last four months of 1915, with some 39 reported cases of the disease, I have a record of 21 carriers found as well as 3 missed cases. During the first five months of 1916, with some 90 cases of the disease, I have a record of 10 carriers and 2 missed cases.

#### CONCLUSIONS.

I have practically abolished recurrent cases, made infrequent secondary cases, and lessened reported cases, by demonstration of the carriers of convalescence and the carriers previously having had the disease and by isolating these carriers.

Results of the so-called grading of quarantine does not depend on the quarantine, but upon the fact as to the presence of the carrier being within or without the family circle.

Full liberty may be safely given to all contacts who are free from the signs of the disease at the time of isolation of the one sick and the carrier.

Control of scarlet fever will be found to lie in the supervision of those who have previously had the disease, at and during those periods when with intercurrent infections they again

show the buccal-pharyngeal signs of scarlet fever. Secondly, missed cases and the convalescent reported cases are of equal importance.

### Society Report.

#### BOSTON SURGICAL SOCIETY. (Incorporated.)

##### TWELFTH MEETING.

A clinical meeting of the Society was held on Monday, April 3, 1916, at the Children's Hospital, at 10 A.M.

Cases were demonstrated by members of the staff of the Children's Hospital as follows:

I. Tuberculosis of the Metaphysis with Subsequent Extension Into the Epiphysis of the Femur. DR. LOVETT.

II. Apparatus devised as a combination of the Bradford frame and plaster, for the fixation and suspension of a child with fracture of the spine. DR. LOVETT.

III. A case recently operated upon for paralysis of the gluteus medius following poliomyelitis with a bad limp. The tendon of the vastus externus had been sutured with sixteen strands of No. 10 silk, four inches long, to the crest of the ilium. DR. LOVETT.

IV. A case for operation showing the application of a tag to the child's neck, in the ward, corresponding to the operation tag, so there would be no mistake in the operation on the side affected. This was a case of a child of nine years who had infantile paralysis at three years, with anterior tibial paralysis. A demonstration was made of the method of measuring the strength of the muscle pull of the affected muscle, and the peroneus longus was sutured in place of the paralyzed anterior tibial. DR. LOVETT.

V. A very severe case of infantile paralysis in a child with extraordinary deformity from contracture, showing the method of gradual straightening by plaster with wedges and tension straps.

VI. A demonstration of the relative methods of treating by traction and by abduction in fractures of the neck of the femur; illustrated by two cases—one of osteomyelitis, and one of congenital coxa vara. (In this case the mother also had a congenital coxa vara.) DR. LOVETT.

VII. DR. HARMER gave a talk on the treatment of naevus with liquid air and oxygen. He stated that it was not an effective treatment for the cavernous type, and showed two cases of excision of cavernous angioma of the neck.

VIII. DR. HARMER also gave a report on the study of ten cases of spina bifida which had entered the hospital since January 1st; average age, three days. All had meningoceles; all showed paralysis. One case showed a tumor the size of 5 cm. on the buttock, with prolapse of rectum and incontinence.

IX. DR. HARMER also showed a patient cut upon the wrist by a milk bottle. All flexor tendons divided with the exception of the thumb and the median nerve. Remarkably good result at five and

a half months after suture. No splint was used in this case, and motion was begun at once.

X. DR. LADD then demonstrated a case of hare-lip with wide separation of the intermaxillary bone. Age 10 months; operation 10 days before. Dr. Ladd demonstrated a clamp which he uses for guiding the cut in the lip margin, in order that both sides may be symmetrical.

XI. DR. STONE showed a case of Volkmann's contracture following fracture of the clavicle and bandaging of the arm, with sloughing and contracture. Dr. Stone detached the muscles from the internal condyle in order to permit lengthening, and had also done one abdominal plastic flap for contracture of the hand.

XII. DR. C. J. MIXTER showed a case of sarcoma of the bladder, operated upon by sub-peritoneal cystectomy, with closure of the fistula in about one month.

XIII. DR. MIXTER also demonstrated a patient with tuberculous peritonitis treated by injection of nitrogen.

XIV. Another case of tuberculous peritonitis was demonstrated in which the first laparotomy was followed by a re-accumulation of fluid, but the second operation with the use of nitrogen was followed by a satisfactory result.

XV. DR. MIXTER also showed a case for decapsulation for chronic nephritis.

XVI. DR. STONE showed a patient with gangrene of the serotum resulting from infection of the umbilical cord in an infant, and spoke of other cases with extension to the peritoneum and the subcutaneous tissues of the thigh.

XVII. DR. LADD showed a case of imperforate anus in a child 24 hours old.

XVIII. DR. LOVETT showed a case of imperforate anus with recto-urethral fistula.

XIX. DR. LOVETT also showed a case of post-diphtheritic paralysis of obscure onset.

XX. DR. C. J. MIXTER then operated for tuberculous peritonitis by injection of nitrogen.

The meeting then adjourned.

ROBERT B. GREENOUGH,  
*Secretary.*

## Massachusetts Medical Society.

### DISCUSSION OF SYMPOSIUM ON GOITRE.\*

DR. M. C. SMITH, Lynn: I wish to make a few remarks on this subject from the standpoint of the dentist. Hypothyroidism is today being recognized as a dental disease, and should be treated by the dentist. I do not think that there is any one symptom of insufficient thyroid secretion that is so thoroughly manifest as the condition in the mouth. The number of children that come to the dental clinics and to the office with irregular dentition, and with delayed and erratic dentition, and decayed teeth due to faulty metabolism of the thyroid, is becoming appalling, and something should be done to try to correct it before the teeth are erupted.

From the time of birth until the child is seven or eight we can tell almost the exact time when the child suffered most from the lack of thyroid secretion, and the fixation of lime salts in the teeth, and if the child suffered from lack of mineral salts in the teeth, it is reasonable to infer that the other bones also suffered.

In some children the benefit gained from the administration of thyroid is most marked, especially in cases of delayed dentition and in children bordering on cretinism. It has been my practice for some years to give thyroid to all children suffering with adenoids, enlarged tonsils, and to all cases of orthodontia. I never think of beginning to regulate the teeth of a young child without first giving thyroid, and I think the results justify the treatment.

DR. THEODORE C. JANEWAY, Baltimore: I want to express my very great interest in the various papers of the afternoon. I sat here quite fascinated by all that I have heard, and I want to congratulate the Society on such an admirable symposium.

There is one point which seems to me is reinforced by some results of the investigations which we have heard of this afternoon, and which we can all take to heart, even though we cannot ourselves apply the method of calorimetry. That is the very great significance of loss of weight as a symptom of hyperthyroidism. To any one who will pay attention to it, the effect upon the metabolism, which plays so important a part in the picture of the disease, can be detected early. I am quite sure that many patients are passed over merely because of the failure to recognize the significance of a continuing loss of weight, in spite of preserved appetite, and apparently for a time preserved energy and bodily activity. I have seen that symptom, when recognized, permit of successful medical treatment, in spite of the fact that I agree that, for the patients studied nowadays in hospitals, surgery is usually necessary. One of the reasons for the difference of opinion between surgeons and medical men is that we tend more and more to treat our patients in hospitals. We think in terms of the hospital population.

In hospital patients with exophthalmic goitre, as with most hospital patients with gastric ulcer, operation is a short cut to a cure. It is most desirable where the time consumed by protracted medical treatment of any kind is unlikely to be afforded. The patients will usually break off medical treatment before a sufficient period has elapsed. It is often the case that two years is necessary for the successful medical treatment of exophthalmic goitre. In private patients who can and will cooperate, however, the medical man may accomplish cures, and cures which are permanent, however, and Dr. Cannon's work is bringing more hope in that regard. Such patients must be carefully selected and still more carefully managed.

We must go back to the thyroid gland for the

\*Continued from the issue of the JOURNAL for October 1909 (Vol. clxxv, page 569).

explanation. All the surgeon does—and of course it is a most important thing—is to break the vicious circle at its weakest point by the removal of the over-secreting gland, which is continually increasing the disturbance by its particular contribution.

One other point has interested me very much, and that is Dr. Boothby's statement about cases of myxedema. I have been very much impressed, in seeing mild cases of myxedema in consultation, with the frequency with which they are mistaken for chronic nephritis. Three things account for this,—the regular presence of albuminuria and hyaline casts, with low specific gravity of the urine, the edema of the lower extremities and the change in the color of the skin; also, in many cases, the occurrence of headache as a symptom, and the frequent moderate hypertension. I am not sure that I agree with Dr. Boothby that we may look on hypothyroidism as the cause of chronic nephritis, but I think, rather, that the diagnosis is wholly erroneous in some cases of chronic nephritis, and that the patient really has myxedema.

#### REPORT OF COMMITTEE ON WORKMAN'S COMPENSATION.

THE conditions under which the medical provisions of the Workman's Compensation Act have been operating in many of the industrial centres, have been more and more regarded by the physicians of the State as unsatisfactory. A belief that the injured employee was not getting in many places such medical services as were his due, has interested the profession sufficiently to create a strong demand that the State Homeopathic Society and the Massachusetts Medical Society investigate the matter and attempt to modify such conditions as seemed unfair. These investigations and the changes indicated by the results of the investigation will be under the direction of a Central Consolidated Committee. The nucleus of this committee is the Workman's Compensation Committee of the Massachusetts Medical Society, to which has been added a representative from each district society and, by invitation, three members of the Massachusetts Homeopathic Society (hereafter mentioned as the Workman's Compensation Committee.)

The events leading up to the formation of this committee and its personnel will be found in the issues of the JOURNAL for Sept. 28 and Oct. 19. There has also been considerable discussion of the subject in other issues of the JOURNAL, which, as the official organ of the Massachusetts Medical Society, places its columns at the disposal of all who desire to discuss important professional subjects.

The Workman's Compensation Act Committee has divided itself into sub-committees. The

chairman of the Workman's Compensation Committee, and also of the sub-committee on legislation and finance, is Dr. A. N. Broughton of Jamaica Plain (Boston), and its secretary, Dr. J. A. Mehan, Lowell. Sub-committees on the following matters have been appointed. Legislation, Dr. Broughton, chairman; Finance, Dr. Broughton, chairman; Information and Statistics, Dr. Snow of Newburyport, chairman; Publicity, Dr. Mehan of Lowell, chairman. These appointments and addresses are given in detail because the members desire to receive all kinds of information and criticism which their fellow workers think useful to the cause, or to them personally. In many of the districts there are district committees organized to cooperate with the central committee, and it is desirable that each district society appoint such committees, and also each city medical club.

The Compensation Committee has held two meetings, and its sub-committees two. There is an agreement that much of the unsatisfactory working of the medical provisions of the law is due to the injured employee being obliged to accept the services of a physician employed by a commercial company, or forego the medical benefits of the act. That this has been regarded by the workers as detrimental to their best interests is evidenced by their organizations introducing and supporting in the legislature each year bills calling for an amendment of the act to give them freedom to employ the physicians in whom they have confidence. The workman is the important factor, and the careful attention which will make him as comfortable as possible and return him to work at the earliest possible day is, of course, his desire, and the desire of the medical profession. The knowledge that the physicians hired to care for him usually do so at a less rate than such services demand in the open market, does not increase his confidence in their efficiency. In this belief the physicians of the State (including the members of this committee) and the wage-earners are in complete accord.

The committee on statistics wishes all the information any of the readers of the JOURNAL can give on any of the phases of the working of this act and also upon any other subject affecting the practice of medicine.

With the letter from the chairman of this committee telling each physician in the State of this work, will be enclosed a blank asking in detail for the information the committee thinks most important at this time. It is hoped all physicians will give this matter of information the consideration it deserves. It is important now and may be increasingly so in future years. The success of this movement is so largely dependent upon the work of each physician in his own locality that the committee urge all to persistent action who believe, with the great majority of the profession, in these amendments.

## Book Reviews.

*A Practical Treatise on Infant Feeding and Allied Topics for Physicians and Students.* By HARRY LOWENBURG, A.M., M.D., Assistant Professor of Pediatrics, Medico-Chirurgical College of Philadelphia. Illustrated with 64 Text Engravings and 30 Original Full-page Plates, 11 of which are in colors. Philadelphia: F. A. Davis Company. 1916.

The author, in this work upon infant feeding and allied topics, comes out very strongly in favor of breast-feeding. He shows that far more babies can be fed on the breast than now are, and that the unnecessary cessation of breast-feeding is the cause of many disturbances of digestion and not a few deaths. His directions for the modification of the breast milk are, however, hardly in accord with our present knowledge of the subject. His general discussion of "percentage" and "calorie" feeding is very satisfactory. In spite of this, however, he makes relatively little use of percentages in his methods of feeding and treatment. He advises the giving of skimmed milk mixtures in the beginning, gradually working to whole milk mixtures. He advocates the use of cane sugar as a routine measure. He shows his familiarity with the ideas of the German school of pediatricians, but in general follows the so-called American ideas. He differs especially from the German school in recognizing that protein, as well as fat and sugar, may cause disturbances of digestion. He emphasizes very strongly the importance of individualization and experience in the artificial feeding of infants, and in this connection advises the use of the term "adaptation" rather than that of modification of milk. He constantly emphasizes the importance of the examination of the stools in regulating the diet both in health and disease, and also recognizes the important part which bacteria play in the etiology of the disturbances of digestion. We regret that he recommends several of the proprietary foods in the treatment of diseased conditions in babies. We believe that it is unnecessary to use these foods, and that the same, or better, results can be obtained in other ways.

After discussing Feeding, he gives chapters on Infantile Atrophy, Rickets, Scurvy, Vomiting, Constipation, Diarrhea, Spasmophilia, The Exudative Diathesis and Pyloric Obstruction. It seems to us somewhat improper to treat of vomiting, constipation and diarrhea as if they were diseases, in the same way as rickets and scurvy. It would seem better to treat them as symptoms of the disturbances of digestion. He believes that spasm of the pylorus is the cause of hypertrophy, and states that clinically all cases of obstruction at the pylorus become oper-

ative when sufficient aliment fails to reach the intestines. This seems to us a very reasonable ground to take. The book closes with a chapter on special methods of treatment. There are many pictures, almost all of which are original and very good.

*Painless Childbirth Eutocia and Nitrous Oxid-Oxygen Analgesia.* By CARL HENRY DAVIS, M.D. Chicago: Forbes and Company. 1916.

The first part is a short review of the various attempts to make childbirth painless. In the second, the author gives some very pertinent facts on obstetric mortality and morbidity. The third part is taken up with the technic of the use of nitrous oxid-oxygen analgesia. The author is enthusiastic about nitrous oxid analgesia but his enthusiasm goes beyond bounds when he states "there is no logical reason why women should suffer during labor." The book is welcome because it stands out in such contrast to the unscientific books which have appeared during the past year about "twilight sleep" and painless childbirth. Although the reviewer cannot agree with all the conclusions and feels confident that later the author will at least modify some of them, the book is an excellent monograph on the subject.

*A Guide to Gynecology in General Practice.* By COMYNS BERKELEY, M.A., M.D., M.C. (Cantab.), F.R.C.P. (Lond.), and VICTOR BONNEY, M.S., M.D., B.Sc. (Lond.), F.R.C.S. (Eng.), M.R.C.P. (Lond.) London: Henry Frowde and Hodder and Stoughton. 1915.

Under the modest title of a Guide to Gynecology in General Practice, Berkeley and Bonney present an excellent book. It is written for the practitioner, but undergraduate students will find it valuable in their clinical training. Its purpose is to supplement textbook and lecture and it contains no details of operative technic. It attacks the problems from the point of view of the practitioner and is therefore likely to prove very useful.

The subject-matter is considered under five heads: Examinational Methods, Significance of Symptoms, Interpretation of Physical Signs and Methods of Treatment; finally, the Medical-legal Aspect of Gynecology is discussed. The fifth part is a welcome addition, though the difference between the law in England and in this country makes this section of less value to American physicians, and the example of the authors is one that deserves commendation.

The book is to be recommended highly for clearness of presentation, breadth of view and soundness of judgment. The illustrations are numerous and excellent. It is a pleasure to see such an adequate presentation of the subject.

## THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, NOVEMBER 9, 1916

### EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*

GEORGE G. SMITH, M.D., *Assistant Editor.*

WALTER L. BURRAGE, M.D., *For the Massachusetts Medical Society.*

### COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D.

HARVEY CUSHING, M.D.

DAVID L. EDSELL, M.D.

REID HUNT, M.D.

ROGER I. LEE, M.D.

ALLAN J. McLAUGHLIN, M.D.

ROBERT B. OSGOOD, M.D.

MILTON J. ROSENAU, M.D.

EDWARD C. STREETER, M.D.

E. W. TAYLOR, M.D.

### ADVISORY COMMITTEE.

EDWARD C. STREETER, M.D., *Boston, Chairman.*

WALTER F. BOWERS, M.D., *Clinton.*

ALGERNON COOLIDGE, M.D., *Boston.*

HOMER GAGE, M.D., *Worcester.*

JOEL E. GOLDSWORTHY, M.D., *Boston.*

LYMAN A. JONES, M.D., *Boston.*

ROBERT B. OSGOOD, M.D., *Boston.*

HUGH WILLIAMS, M.D., *Boston.*

ALFRED WORCESTER, M.D., *Waltham.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.50 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## THE PROPAGANDA OF ANTI-VACCINATION.

THE attention of members of the Massachusetts Medical Society, and of all other physicians, is called to the letter from Dr. Woodward, President of the Society, published in the correspondence column of this issue of the JOURNAL. The annual recurrence of anti-vaccination propaganda does not arouse, as it should, the active opposition of the medical profession. Each year the margin by which anti-vaccination legislation is defeated seems to be diminishing. Ultimate passage of such legislation, however, could be due only to the apathy of physicians and to their failure to present to the public and to legislators, collectively and individually, the truth about vaccination and the fallacy of the anti-vaccination movement. Committees on medical legislation can accomplish little unless their action is supported by

the firm and unanimous voice of the profession which they represent. During the coming season many legislative matters of medical importance, in addition to that of anti-vaccination, will be under discussion and will require the intelligent study of members of the profession, if they are to be decided with best regard to the public welfare. As in the past, it will be the effort of the JOURNAL to assist physicians in this way by presenting the facts on both sides of every question, with such discussion as may be helpful to its readers in the formation of individual opinion. Only by the concerted and active coöperation of all, however, can there be developed a genuine medical public opinion which shall be of value and power in the direction of medical legislation for the common good.

## THE WORK OF DISTRICT MEDICAL SOCIETIES.

AT this time of year the chairmen and secretaries of various district medical societies, and others, are busily engaged in preparing their yearly programs of subjects to be discussed. This is an important piece of work, and we believe it does not always receive the mature and careful consideration which it deserves. The choice of subjects is far too apt to be left to the individual preference of the chairman or secretary, resulting in an ill-balanced list of papers and important omissions.

Medical societies have two very definite functions: (1) to promote social intercourse among the members, and (2) of more importance, to disseminate knowledge and to present facts and give information on important and vital subjects which the general practitioner can get in no other way. Individual preferences of this or that group of physicians ought not to be too seriously considered at these meetings. It is very likely that any group of busy general practitioners, tired out after a hard day's work, would be vastly more interested in a thrilling account of life in the trenches and war surgery than in a discussion of the importance of preventing the ravages of syphilis or the early diagnosis of tuberculosis. It is manifest, however, that the two latter subjects are of infinitely greater importance than the former.

This is strikingly illustrated in the programs of a certain large medical society in this state, which neither in its program for the coming year nor in its programs for the past three years, has included the subject of tuberculosis for the reason frankly given, that tuberculosis would not draw a crowd and that the doctors are not interested in it. To many this would not appear a sufficient reason for such an important omission. In the programs of 14 district medical societies in this state for the year 1915 there were 97 subjects discussed. Of these, 67 were what might be called distinctly clinical subjects, while 30 were non-clinical and dealt with topics relating to the broader aspects of medicine. Of this last group, 16 out of the 30 were papers relating to the present war, leaving 14 papers out of a total of 97 which took up the subjects of public health and preventive medicine. In view of the present tendencies of modern medicine this hardly seems a just proportion. We believe that more attention should be given to such subjects as medical education of physicians in the early diagnosis of cancer, tuberculosis and similar diseases, the improvement of our medical schools, the administrative control of the venereal problem, health insurance, etc., and we also believe that the majority of general practitioners in this State will agree with this point of view.

### THE NAVY AS A FIELD FOR MEDICAL WORK.

THE attention of graduates in medicine under thirty-two years of age should be earnestly called to the opportunities offered by the Medical Corps of the United States Navy as a special field for professional work. Legislation has recently been enacted which will provide for approximately three hundred additional medical officers in this corps, giving immediate opportunity for work and advancement to those properly qualified.

The naval medical officer should be regarded as a specialist, concerned, it is true, with many departments of medicine, but approaching them all from a unique standpoint. His patients belong to a selected group and, under conditions of service in peace or war, offer particular clinical problems. Moreover, as such a group, the material afforded gives especial opportunity for work in preventive medicine and for dis-

coveries in scientific branches of great value in the advancement of medical knowledge. The Navy, like the Army, constitutes a group of material under definite conditions of discipline which make possible research on a scale that cannot often be attempted under the uncontrolled conditions of civil life. Hence it is, that the appeal of the naval medical service is not solely to the instincts of a practitioner or to the love of adventure, but to those of the research student in medicine as well, whose aptitudes lie in the field of scientific medicine.

These considerations represent merely the field of opportunity to the individual; but there should not be forgotten also the opportunity of service which the naval medical officer enjoys in the diffusion of ideas in hygiene and allied medical branches, not only in his own country, but throughout the world.

The United States Navy has recently issued a circular for the information of persons desiring to enter its medical corps and another circular listing the physical qualifications required. Examinations for these positions are to be held in several of the coast cities of the United States, both East and West, and also in Chicago. Full particulars regarding the time and places of these preliminary examinations, with descriptive literature and the circulars mentioned above, may be obtained by addressing Dr. W. C. Braisted, Surgeon-General, United States Navy Department, Washington, D. C.

### THE CUTTER LECTURES.

IN another column of this issue of the JOURNAL we publish a brief account of the life and work of Dr. John Clarence Cutter, founder of the Cutter lectureship on preventive medicine at the Harvard Medical School. The first quin-quennium of this valuable institution has already been completed and the lectures thus far given, by men of distinction in the medical profession, have proved genuine contributions to the knowledge and exposition of the science of preventive medicine. In this connection, therefore, it is of interest to publish also the following list of Cutter lecturers with the dates and titles of their papers.

1. Dr. Wm. H. Park, March 13, 1912. Observations on Dosage and Methods of Injecting Anthrax in the Treatment and Prevention of Diphtheria and Tetanus.
2. Dr. John F. Anderson, May 9, 1912. Some Re-

- cent Advances in Our Knowledge of Certain Infectious Diseases.
3. Dr. George C. Whipple, March 31, April 2, April 7, 1913. The Use of Vital Statistics with Truth, with Imagination, with Power.
  4. Dr. Mark W. Richardson, May 12, 1913, and May 14, 1913. Health Administration.
  5. Dr. Charles V. Chapin, March 20, 1914. Science and Sanitation.  
March 27. Efficiency of Public Health Measures.  
April 2. Organization of the Health Department.  
April 9. Research and Publicity.  
April 16. Nuisance Problems.  
April 30. Contagious Disease Problems.
  6. Dr. Cressy L. Wilbur, March 25 and 26, 1914. Vital Statistics in Massachusetts and the U. S.
  7. Dr. Joseph Goldberger, April 2, 1915. Diet and Pellagra.
  8. Dr. Victor C. Vaughan, April 14, 15, and 16, 1915. The Phenomena of Infection.
  9. Dr. George W. McCoy, April 3, 1916. The Public Health Aspects of Leprosy.
  10. Dr. Simon Flexner, April 26, 1916. The Finer Adjustments of the Immunity Reactions to Recovery from Infection.

### PROGRESS OF POLIOMYELITIS.

DURING the past week the Massachusetts epidemic of poliomyelitis has, on the whole, declined, although the daily number of new cases still remains considerable. The total number of cases during the month of October was 703, as compared with 623 in September, 253 in August, and 107 in July. More careful statistical investigation has shown that during the month of August there were 67 deaths from this disease in Massachusetts instead of 39, as had previously been reported. These deaths were distributed among the several cities and towns as follows: Boston twenty; North Adams, ten; Springfield, five; Pittsfield, three; Somerville, three; Easthampton, two; Medford, two, and the following one each: Agawam, Amesbury, Bourne, Brookline, Dudley, East Longmeadow, Fall River, Georgetown, Greenfield, Haverhill, Holyoke, Lawrence, Littleton, Lowell, Lynn, New Bedford, Newburyport, Newton, Northampton, Southwick, Westfield and Worcester. In September there were 151 deaths, of which 57 were in Boston. Accurate data are not yet available for the number of deaths in October. During the first four days of November there were 45 cases.

The following statistics relative to the distribution of epidemic cases throughout the United States have been compiled from a recent weekly bulletin of the United States Public Health Service:

"Massachusetts, 1761; Maine, 104; Vermont, 35; New Hampshire, 53; Connecticut, 812;

Rhode Island, 179; total, 2610. In New York City in the period aforementioned, there have been 9216 cases, of which 2373 were fatal.

"A comprehensive idea of the way the fingers of this disease have been laid upon the entire country may be gathered by figures from the report for widely separated sections.

"Nevada and New Mexico, from July 1 to Sept. 24, have been spared altogether, while Wyoming has seen only four cases from July 1 to Sept. 30; North Dakota, 8, July 1-September 25; and Utah 5, August 1-31—a gentle touch in the Rocky Mountain zone.

"New York State, exclusive of New York City, has a total of 3495. Adjoining the island of Manhattan, New Jersey registers 3917, and Pennsylvania, little separated, has 1561. Then the statistics taper in going South. Delaware, small in area, 57; Maryland, 254; South Carolina, 113; Alabama, 151; Louisiana, 31. Only eight cases were recorded in Florida.

"Illinois, in the Middle West, is relatively high, with 749 cases. Iowa has 198, Indiana 150, and Ohio 400.

"California with 50 cases, Oregon with 14, and Washington with 20, display no very great trouble along the Pacific slope.

"Indiana, Illinois and Ohio have been mentioned. Other Lake States showing some pressure are Michigan, 423, and Minnesota, 784.

"Statistics from all States practically all begin from July 1. They end variously at September 25, October 14 and October 17. In some States the disease is present, but its extent is not recorded. On this basis the country-wide total is 25,266 cases."

At the forty-fourth annual meeting of the American Public Health Association, held last month in Cincinnati, Dr. Thomas F. Harrington, of Boston, deputy commissioner of labor in Massachusetts, presented on October 26 a paper dealing with 42 cases of chemical poisoning from gas and fumes, reported during the past year to the Massachusetts State Board of Labor and Industries. Basing his argument upon a discussion of these cases, Dr. Harrington is reported to have advanced the theory that poliomyelitis is a disease due not to a microorganism, but to a chemical intoxication. In the daily press Dr. Harrington is quoted thus:—

"All observations point to one conclusion only, namely, that they are one and the same disease. Paralysis, neuroses, disturbance of movements, diminution of muscular power, twitching, wasting of muscles, hypersensitiveness, numbness and loss of sensation of the skin, eruptions on the skin, digestive disturbances, sore throat, bronchitis, psychoses, poliomyelitis, sclerosis of the cord, delirium, convulsions, coma and death constitute a group of symptoms com-

mon to both infantile paralysis and gas and fume poisoning.

"Dizziness, unconsciousness, mental confusion, convulsions and death have been reported among chauffeurs and others working on or about automobiles, in the open air as well as in confined spaces. Although cases of infantile paralysis have been recognized in many countries for years, nevertheless its prevalence in an endemic and epidemic form dates from the introduction and wide use of the automobile.

"In other words, in infantile paralysis we are dealing with a chemical agent and not with a microorganism, a condition identical to that met with in poisoning by the fumes of lead, mercury, arsenic and antimony.

"These gases and fumes are heavier than air and travel close to the ground, with a tendency to seek rivers, streams and ponds. This characteristic of these chemicals explains the greater prevalence of infantile paralysis among susceptible children living in lower parts of houses, and also the occurrence of epidemics of this disease among animals and fowl living in the ground stratum of air.

"The most successful treatment for gas and fume poisoning promises the best results in the treatment of infantile paralysis, namely, neutralize the acid condition by saline solutions—locally and intravenously, transfusion of blood, oxygen inhalations, hot baths, rest and warmth; for the later stages, rest, heat, massage, electricity, splints, hygiene.

"The preventive measures successful in combating industrial poisoning from gases and fumes suggest the line of action most promising in reducing the ravages of infantile paralysis, viz.: First, a recognition of the dangers in gases and fumes from motor fuel, especially for automobiles, and second, a close supervision by Government control of the nature of fuel used for motor vehicles, gas engines and for domestic purposes, to the end that the poisonous elements shall be reduced to a minimum in petroleum and coal tar products used for purposes of light, heat or power."

The complete report of Dr. Harrington's paper and the further exposition of his theory will be awaited with interest.

#### MEDICAL NOTES.

**GIFT TO COLUMBIA DENTAL SCHOOL.**—Report from New York states that on October 29 the trustees of Columbia University announced gifts to the sum of \$125,000 for the establishment and maintenance of a dental school and infirmary in conjunction with the University.

**AWARD OF DAMAGES AGAINST A MIDWIFE.**—Report from San Francisco states that on October 24, Justice Murasky of the California Su-

perior Court awarded damages to the amount of \$25,000 against a graduate midwife who, it was alleged, had not exercised proper prophylactic care of a baby's eyes, with the result that it became blind from ophthalmia neonatorum. This verdict is of significance as indicating the opinion of this court, with reference not only to the responsibility of midwives, but to the extent of damages to be awarded for loss of eyesight in a baby.

**CLINICAL CONGRESS OF SURGEONS.**—The seventh annual session of the Clinical Congress of Surgeons of North America was held in Philadelphia during the week of October 23 under the presidency of Dr. Fred Bates Lund of Boston, and in accordance with the program and announcement published in the issue of the JOURNAL for October 5. The usual clinics were held before the several sections of the Society at the various Philadelphia hospitals. In accordance with a vote passed a year ago, adopting a follow-up system in connection with all cases operated before the Congress, a report was presented covering the end-results of the operations performed before the Congress last year in Boston. At the meeting on October 26, a resolution against dichotomy was adopted. It was voted that the next meeting of the Congress shall be held in New York, and Dr. John G. Clark of that city was elected president for the ensuing year. Other officers elected were Dr. George Henderson Dee, Galveston, first vice-president; Dr. Edgar W. Allen, Edmonton, Alberta, Canada, second vice-president; and Dr. Franklin H. Martin of Chicago, secretary general.

The annual meeting and convocation of the American College of Surgeons was also held in Philadelphia on October 27, and adopted a resolution establishing a board of surgical censors to control future admissions to the college. Two hundred and twenty-eight new Fellows were admitted at this session, of whom two were from Maine, four from Connecticut, eight from Rhode Island, and the following nine from Massachusetts: Drs. George D. Bliss, Dorchester; Charles William Bush, Frederick Lafayette Jack, James Krauss, Louisa Paine Tingley and Agnes C. Victor, all of Boston; Gilman Leeds Chase, Clinton; Harry Cleveland Cheney, Palmer; and Ralph W. Jackson, of Fall River. The college now numbers over four thousand Fellows. At the business meeting, Dr. George W. Crile of Cleveland was elected president for the ensuing year, and Chicago was chosen as the permanent headquarters of the organization. It was announced that with the sanction of the United States Government the American College of Surgeons has appointed a commission to make a tour of South America for the purpose of establishing closer relationship between the surgeons of both continents of the Western Hemisphere. The members of this commission are: Drs. Edward Mar-

tin, Philadelphia; A. J. Ochsner and Franklin H. Martin, Chicago; Frank S. Simpson, Pittsburgh, and either C. H. or W. J. Mayo of Rochester, Minn.

#### EUROPEAN WAR NOTES.

**BELGIAN SURGICAL DRESSINGS FUND.**—The Belgian surgical dressings industry has fulfilled so satisfactorily the double purpose for which it was started in March, 1916,—that of giving employment to Belgian women refugees in England, and of increasing the supply of dressings for the army,—that its organizers feel justified in sending out a second appeal, in order to continue the work. Mrs. Erskine Childers, who has undertaken the management of the industry in London, as a branch of her great work for the Belgian refugees there, writes of the appreciation, on the one hand, of the Belgian Red Cross, for the supplies which they receive from the industry, and on the other, of the gratitude of the women for the opportunity given them to do this work, which is naturally most congenial, as by it they are helping their husbands, sons and brothers at the front. The extent of the work is limited only by the amount of funds procured, and Mrs. Childers is eager to increase as well as continue it.

Miss Olive Simes will gladly receive contributions for the Fund, addressed to her at 46 Chestnut Street, Boston.

**MORTALITY FROM WAR AND FROM ALCOHOL.**—Dr. C. W. Saleeby, F.R.C.S., F.R.S., a well-known English physician, has recently issued a statement relative to the comparative mortality due to war and to the use of alcohol by a community. He states that the annual loss of life in Britain amounts to three-fourths of the loss during the first year of the European War.

"The first year of the great war cost us about eighty thousand fine lives of our soldiers and sailors.

"But during every year of peace, alcohol takes at least sixty thousand lives in this country. On the most moderate reckoning it is responsible for one-seventh, or about 14% of the whole death rate. This toll of over a thousand lives a week, year in and year out, is three-fourths of the toll exacted by the greatest war in history.

"Estimating from the average size of a family and the known death rate from alcohol, we find that this destroyer of the people, by its destruction of husbands and fathers, makes 45,445 widows and orphans in England and Wales every year, or over 124 every day. These figures are an under-statement, for they do not recognize the fact that the mortality due to alcohol is really much higher among men than women.

"We have in this country an infant mortality of about one hundred thousand per annum,

and a mortality of infants before birth which is at least as high. It is estimated that not less than half of this ante-natal mortality, namely, fifty thousand lives per annum, is due to syphilis. Over the whole of this colossal loss of life, before and soon after birth, amounting to not less than 200,000 lives annually, is the trail of alcohol, either doing its deadly work hand in hand with syphilis or destroying life directly on its own account.

"Obviously, therefore, the abolition of the mortality directly and indirectly due to alcohol would vastly more than compensate for the unprecedented loss of life due to the deadliest war in history."

**WAR RELIEF FUNDS.**—On Nov. 4 the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund .....	\$162,906.12
French Wounded Fund .....	131,312.85
Armenian Fund .....	105,681.21
Serbian Fund .....	104,649.07
Surgical Dressings Fund .....	55,259.66
Polish Fund .....	46,748.78
Italian Fund .....	26,358.54
Permanent Blind Fund .....	21,310.94
Prince of Wales Fund .....	16,015.68
P. S. D. Fund .....	9,814.63
French Phthisis Fund .....	5,834.50

#### BOSTON AND NEW ENGLAND.

**WEEK'S DEATH RATE IN BOSTON.**—During the week ending Saturday noon, Nov. 4, 1916, the number of deaths reported was 222, against 205 for the same period last year, with a rate of 15.22 against 14.28 last year. There were 36 deaths under one year of age, against 39 last year, and 61 deaths over 60 years of age, against 62 last year.

The number of cases of principal reportable diseases were; diphtheria, 39; whooping cough, 4; scarlet fever, 13; typhoid fever, 2; measles, 14; tuberculosis, 32.

Included in the above were the following cases of non-residents: diphtheria, 9; scarlet fever, 3; typhoid fever, 1; tuberculosis, 5.

Total deaths from these diseases were: diphtheria, 5; measles, 1; whooping cough, 1; tuberculosis, 16.

Included in the above were the following deaths of non-residents: diphtheria, 1.

**BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.**—The Annual Meeting of the Boston Association for the Relief and Control of Tuberculosis is to be held at the Twentieth Century Club, Boston, on Friday, November 10, at 3.30 p.m.

The three leading speakers are Edward R. Baldwin, M.D., director of the Saranac Lake

Laboratory and president of the National Association for the Study and Prevention of Tuberculosis; Homer Folks, LL.D., director of the National Association and secretary of the State Charities Aid Association of New York; and Lee K. Frankel, Ph.D., sixth vice-president of the Metropolitan Life Insurance Company.

The subject to be treated is "Tuberculosis from the Medical, Social and Industrial Point of View," Dr. Baldwin speaking from the medical point of view, Mr. Folks from the social and Mr. Frankel from the industrial. The meeting should be of unusual interest to physicians. It is open to the public.

**BERI-BERI IN NEW BEDFORD.**—Report from New Bedford, Mass., states that on October 24, six cases of beri-beri were discovered aboard a schooner recently arrived in that port from the West African coast. The patients were the captain, two officers and three sailors of the crew.

**REPORT OF BOSTON HEALTH DEPARTMENT.**—A recently published monthly bulletin of the Boston Health Department contains data showing a considerably larger total mortality in this city during the first nine months of this year than during the corresponding period in 1915. The following abstract of the report indicates the distribution of this mortality.

"Total deaths in Boston for the thirty-nine weeks of this year are 10,054, compared with 9337 for 1915. Non-resident deaths, included in the total, have so far numbered 1373, as compared with 1269 a year ago. Pneumonia has claimed 1308 victims this year, as against 1127 last year; cancer, 679 this year, compared with 708 last year; heart disease, 1355 this year, compared with 1245 last year; diarrhea and enteritis, under two years, 300 this year, compared with 348 last year.

"Deaths from communicable diseases fall slightly lower than last year's total, with infantile paralysis excluded. There have been 1212 such deaths this year, compared with 1230 a year ago. Diphtheria last year resulted in 175 deaths. So far this year there have been 137. Scarlet fever last year resulted in 75 deaths, and only 34 this year. Measles last year resulted in 32 deaths, and this year 91. Typhoid fever last year was responsible for 31 deaths, and this year the number has been 13. Whooping cough last year claimed 73 deaths and this year 60. Tuberculosis last year resulted in 841 deaths and this year 877.

"This has been a very active year with measles, a total of 5128 cases having been reported, compared with 4824 last year. This is the only instance that the total in communicable diseases was larger than last year. Diphtheria shows a falling off of 363 cases; scarlet fever, 1042; typhoid fever, 127; whooping cough, 248; and tuberculosis, 160."

## Obituary.

### DAVID FRANCIS LINCOLN, M.D.

WITH the death of Dr. David F. Lincoln, which occurred suddenly on Tuesday, October 17, there passed away a man who deserves well to be remembered by the medical profession of this city. But few remain who could call themselves, in a distinctive sense, his colleagues; and the life that he had led for many years before his death was so quiet, and so remote from the world of modern medicine, that the younger members of our fraternity have had little opportunity to become familiar even with his name, much less to make themselves aware of his fine qualities of heart and mind.

Dr. Lincoln was born in Boston on January 4, 1841, and received his primary and secondary education in our Boston schools. He entered Harvard College at the age of sixteen, with the Class of '61, in company with many men who afterward became distinguished. Those whom I happen to associate especially with him are Henry P. Bowditch, Wendell P. Garrison, N. P. Hallowell, James K. Stone, and Edward Wigglesworth; but class feeling in general was strong in him. Then, as later, he was shy, quiet, and retiring, but he always commanded the respect and friendship of the best of his associates.

Graduating just as the Civil War broke out, he enlisted in the Navy, remaining in that service for a period of one and one-half years. He then studied medicine in the Harvard Medical School, and in 1865 served as house officer at the Boston City Hospital, in company with Drs. Edward G. Loring, Michael Gavin, John Dole and Clarence J. Blake. A trip to Europe followed, and he spent two years there in medical study, leaning toward the specialty of neurology. It was at this time that I first learned to know him well, and became attracted to him for the independence, loyalty, and intrinsic interest of his character.

After his return to America, Dr. Lincoln practiced medicine for several years, as a specialist in neurology. It soon became evident, however, both to him and to his friends, that, with his habit of silence on the one side, and blunt speech on the other, he was not likely to make his way as a practitioner, although every one who knew him well recognized, underneath his exterior of silence, remarkable qualities of learning, gentleness, even playfulness, and broad, kindly interests in humanity.

Finding that medicine did not go, he tried his hand at teaching, for which in certain ways he was well fitted. Latin and Greek were his specialties in this profession, and he taught them in private schools and also at Hobart College in the pleasant town of Geneva, N. Y., where he filled an important position, with happiness and success.

Returning to Boston, he occupied himself

with various matters referring to public health and hygiene. A very early and warm friend of his was the late Mr. James M. Barnard, who, like himself, was an ardent and single-minded lover of progress and a man who worked better upon his own lines than in harness with other men. For several years these two served as the president and secretary and chief helpers of a society devoted to the interests of public health, to which a number of other friends of Dr. Lincoln, including myself, also belonged.

For many years Dr. Lincoln was a true friend and helper of the George Junior Republic, where he made frequent visits, and with the workings of which he made himself intimately familiar. At the same time he espoused the cause of backward children in the public schools, spending a great deal of time in the actual teaching of certain of them, and doing what he could to see that the needs of all were appreciated and met.

For a good many years before his death he lived in small and very modest quarters on one of the quiet little streets of Beacon Hill, better known to our ancestors than to ourselves, and here he made himself the personal friend, to a degree that but few even of those who stood nearest to him were aware, of many children whose acquaintance he had made either in the schools or in the neighborhood of his rooms. He had long been in the habit of working in the North End Union, with Mr. Samuel F. Hubbard, and his neighborhood work was a logical extension of this. These children, of various nationalities and color, he stimulated to read and study, and aided to form clubs. Altogether, he played a part in their restricted lives which was of priceless benefit to them, and the affection they gave him testified to their appreciation.

Dr. Lincoln was always a reader and a student, and he had a first-rate power of literary appreciation and criticism. This, together with the genuineness of his interests, made him a very agreeable talker on all matters which he had set himself to study.

On the morning of October 17 he was found sitting in his chair, so quietly, and with such a natural expression, that it seemed, at first, impossible to think of him as dead. His books and papers were around him, and his relatives who took charge of them found a number of charming bits of writing of which they had not known.

His only published work of any magnitude, so far as I remember, was a compendium of physiology, for use in schools. This was an excellent book and filled a real need.

But quietly though he lived, the part which he played in the community was real and important, and one could say of him with warmth and emphasis,

"Nec vixit male qui natus moriensque fefellit."

JAMES J. PUTNAM.

## Correspondence.

### THE PROPAGANDA OF ANTI-VACCINATION.

Worcester, Oct. 30, 1916.

Mr. Editor:—

The enclosed letter with its startling contribution to the etiology of infantile paralysis deserves publicity were it only to emphasize the colossal impudence of the person who signed it.

Its third paragraph does, however, state the exact truth and I wish at this time to call upon every member of the Massachusetts Medical Society to constitute him- or herself a committee of one to interview those who are to be members of the next legislature, to impress upon them the importance of retaining the present law and the punishment sure to follow its repeal.

Very sincerely,

SAMUEL B. WOODWARD, M.D., *President*,  
Massachusetts Medical Society.

720 Tremont Temple, Boston, Mass.,

Oct. 20, 1916.

Dear Dr. Woodward:—

The psychological moment to repeal the Compulsory Vaccination Law is the next session of the Legislature,—owing to the tremendous excitement over infantile paralysis which many experts believe is the inevitable outcome of generations of vaccination.

We need money. If everyone in sympathy with our cause will do what they can to help we can win out this year!

Last year we practically won with a vote of 127 in our favor to 105 against, at the second reading of the bill. This was the largest roll-call in the history of the commonwealth, not even excepting the election of the Speaker of the House. I mention this to show you the tremendous interest in and pressure brought to bear on our measure. At the third reading of the bill the opposition brought every ounce of their power against us, and we only lost by a few votes. Therefore we have reason to feel proud of the splendid fight we made!

We must have funds for office expenses, for a paid worker to cover the state, which means traveling expenses, literature, etc.; all of which counts up.

As in past years, I stand ready to do all the stenographic work gratis. But to win I must be relieved of financial worry which I have cheerfully borne for so many years.

Won't you make a special effort to let your contribution be so large that we can win out this year and be forever rid of this unjust law? May we hear from you at once so that we may push matters all over the state before the legislature convenes?

Faithfully yours,

JESSICA L. C. HENDERSON, *Vice-President*,  
Anti-Vaccination League of America.

### ERRATUM.

In the issue of the JOURNAL for October 26, 1916, (Vol. CLXXV, p. 589) there was an error in the second table in the second column, entitled "Percentage of Total Cases." The first figure in the third column should be "37" instead of "7," so that the table should read as follows:

#### PERCENTAGE OF TOTAL CASES.

	Under 5	5-10	Over 10
Rural Group .....	37	26	37
North Adams .....	76	24	0

### MENTAL PITFALLS OF ADOLESCENCE.\*

BY HENRY R. STEDMAN, M.D.

*Bournewood Hospital, Brookline, Mass.*

So many conditions make for soundness of mind that the field of mental hygiene is a large one; but of all its aspects, none is of more vital importance than its application to the young adult. I shall endeavor, therefore, to give you some idea of the extent, nature and outcome of mental breakdown in youth, its principal causes and the possibilities in the way of its prevention which lie open to the parent, the teacher, the clergyman and the general physician. Widespread information on the subject is plainly called for in view of the large number of youths and girls who are annually admitted to our state and private hospitals for mental disease, and the ignorance of the general public as regards the special form of the disorder which is peculiar to adolescence.

The knowledge and application of the rules of bodily hygiene have, as everyone knows, long protected the adolescent from physical weakness, disease and injury. He is equally well guarded by private and public advice, training and example in the home, the school and the church against moral degeneration. Against ignorance he is educated in this country as in no other. But, against mental deterioration and

breakdown, little or no warning or advice is given him or his parents, as a rule, until he is placed under care in an institution.

Facts about physical disease come home to us. We are familiar with it from everyday observation and experience. We are impressed with accounts of its dangers, its terrors, perhaps, and the numbers of its victims. Mental disease, on the contrary, the most grievous of all diseases, though it may horrify in the abstract, seems very remote as a possibility in our own cases. It is usually the very last calamity we expect to have happen in the family and therefore no precautions are taken against it. If it were not necessary, because of the nature of their illness, to "put away" the mentally afflicted; if the secrecy about their condition, as though it were a disgrace instead of a disease contracted through no fault of their own, did not exist, people would be equally alive to the ravages of mental disease and the importance of the study and application of mental hygiene, or the science of mental health.

### THE FREQUENCY OF DEMENTIA PRÆCOX AND ALLIED CONDITIONS.

How common is morbid mental change in youth, varying from minor states of instability to actual insanity, cannot be stated in percentages. Its lighter shades, although materially affecting the future life of the patient, rarely come under the eye of the institution physician, except in the psychopathic hospital, where incipient and borderline cases are numerous, although full opportunity for their observation and treatment is limited even there. Often the

\* A Popular Lecture delivered under the auspices of the Massachusetts Society for Mental Hygiene in various cities and towns of the State during 1915-1916.

family physician is not consulted for these mild conditions, and when he is he either fails to recognize the disorder or belittles its importance. Consequently there is probably a large number of such persons in danger of mental breakdown who are without advice or other assistance.

But simply taking the known cases of the fully developed disease, the showing is impressive. It is safe to say that the majority of the 14,746 inmates of the Massachusetts state and private hospitals for the insane are cases—mostly chronic—whose disease began when they were young. They had then reached the end of the intellectual lives of which they were capable, became stranded on the rocks of adolescence, and were left mentally incapacitated for life. Of the 3264 *new* cases of mental disease admitted to the Massachusetts hospitals in 1915, 804, or over 21%, were suffering from dementia precox (as the disease we are considering is called) and allied conditions of adolescence. This yearly addition of cases of dementia precox, most of whom become chronic but remain physically well, causes them to accumulate until they soon form the majority of the inmates of our state hospitals. They represent one-third more admissions than the combined totals of all patients whose mental condition is due either to alcohol or syphilis—causes which are very rarely operative in producing this form of mental disease. Of all the classified forms of insanity, moreover, dementia precox claims by far the greatest number of victims.

Here let me say that this mental condition should not be confounded with mental defect or feeble-mindedness proper. It is important to bear this in mind. The mental defective, about whom wide public interest fortunately has at last been awakened, is one who had little or no mind to start with—who has been idiotic or imbecile from birth or infancy. On the contrary, most cases of dementia precox enjoy, up to the time of their breakdown, apparently sound and normal minds. A striking fact is the frequency with which the disease attacks adolescents of marked intelligence and promise. A German authority reports that large numbers of such patients are schoolmasters, the sons of schoolmasters and theologians. Statistics on this point give these figures: 27% men and 21% women had average intelligence before their mental breakdown; 55% men and 66% women had good and even remarkable intelligence; 18% men and 13% women were below the average intelligence, but were not mentally defective.

#### NATURE OF THE DISEASE.

Adolescence, by far the most critical period of mental life, extends approximately from the age of 15 to that of 25. It is in this developmental period, usually towards the end, that dementia precox, the form of mental disorder which is peculiar to youth, begins. It only rarely hap-

pens that it originates later than the completion of adolescence, although in some individuals full mental maturity is not reached before 30. Its name is derived from dementia, which denotes deterioration of the mind through loss of mental power, and precox, premature. In its essence it is an enfeebling of the previously healthy mind, a slow decline of mental strength through gradual weakening of the will and deadening of the emotions or mental feelings. It ends, generally after a few years, in permanent degeneration of the mind, sometimes light but more often pronounced and involving it in more or less complete disorganization. At the outset and throughout the course of the disorder may occur various kinds of mental disturbance appearing as "attacks," such as maniacal excitement, melancholic frenzy, simple depression, states of bodily rigidity (called catatonia), stupor, confusion of ideas and delusional states. Hallucinations, such as seeing or hearing non-existent sights or sounds, and sudden impulsive acts of homicidal or suicidal violence, are not uncommon. These manifestations do not all occur in the same attack although several of them may be combined in a single case.

#### FORMS.

The disease has been divided into several different sub-varieties, but I will only call attention to the simple form which, because of its mild nature, is more frequently met with outside the hospital. The other more pronounced and severe types, common in hospitals, need no further mention. These cases of simple dementia are far less striking and very insidious in their development. The principal feature is change in the youth's character, in the shape of a gradually developing mild apathy and indifference. If in good circumstances, he usually spends his life in indolence, varied by spasmodic and aimless activity, and tends to develop obsessions, antagonisms and anti-social proclivities. The poorer patient so afflicted is often a tramp, a crank, a criminal or a prostitute in the making. The "hobo" class is largely recruited from these mental derelicts. Wilmans, in 127 vagabonds, found 66 cases of dementia precox. This form is a common one, but most of the cases do not reach the hospital for the insane.

#### ITS APPROACH.

Familiarity with the premonitory symptoms of dementia precox is most important, as it is more than likely to be very helpful toward checking or minimizing further trouble if medical advice is sought in time. Therefore, I shall not apologize for giving them in detail. The early indications of the disease, which appear gradually, as a rule, are practically the same whatever form it may afterward assume. In all of my cases, in which intimate knowledge of the earliest manifestations was attainable, lapse in the power of attention—of mental concentration

—has come first. An ambitious student complains: "I cannot any longer wield my mind, which has become my master instead of I being master of it"; "I feel no exuberance as before"; "Everything is a dead weight"; "The feeling clings to me and I cannot fight it off." A bright lad, taking high rank in a preparatory school, grows despondent at finding himself becoming "dull," "stupid," and "weak," and begs to be helped, as his utmost endeavors to go on have failed. The girl in this situation feels for the first time that "she must *struggle* to be like other girls." The patient also becomes more easily fatigued physically than before and loses directive energy and initiative. With increasing mental failure the fruitless efforts are soon abandoned, the mind becomes more inactive, forgetfulness, depression and indolence replacing alertness, ambition and energy. He "wants to be let alone," becomes listless, apathetic, and careless, gradually slipping into a dulled condition of mind. Many become over-conscientious, depressed and self-reproachful. Avoidance of others follows and paves the way for suspicion of those about them, the starting-point it may be of future hallucinations, delusions, and overt acts. Suicidal thoughts may now appear. Adolescent patients of another type, when no longer able to meet even the minor demands of life, and physically fatigued, become easily upset and very irritable, as well as unexpectedly fault-finding and very angry over trifling matters. Marked indecision and constant demand for reassurance regarding the plainest matters of duty are common.

The train of thought naturally becomes interrupted early and may even show signs of the approaching mental confusion of the next and active stage of the disease. Lapse in judgment is shown in the development of unnatural prejudices, sudden and needless alarm at ordinary occurrences. Some patients begin by worrying over their physical condition, believing that their bodies or some bodily functions have undergone a change. Self-control may be early undermined, and strange conduct follows, such, for example, as unnatural and even grotesque infatuations, indiscriminate proposals of marriage, etc.

Sudden and unexpected acts, forerunners of the more pronounced impulsive states of the acute stage, are common, such as exhausting walks with no object after a long period of idleness; unexplained destruction of belongings, etc. Unlooked for transitions of mood and the lack of depth in the patient's depression or anger, characteristic features of the disease through its entire course, are early manifestations, as are also inconsequential speech and aimless effort.

The general appearance of the patient is that of apathy or mild depression, except at times of unexpected and transient animation. Lack of

energy also is constant, except during spasmodic outbursts of misdirected activity or prolonged over-work or exercise. Although such patients, owing to irregular ways of living, sleep more in the daytime, insomnia is developed early. The appetite is capricious. Headache is frequent, and, as Mairet believes, a highly important symptom at this juncture. It is sometimes a severe, persistent and protracted pain, but more often a disagreeable, vague sensation as if, for example, the head were "empty" or "filled with cotton wool." Nightmare is common. A generally weakened, relaxed, poorly nourished bodily condition is usual and is shown in loss of weight, pallor, dilated pupils, low temperature and weak pulse. Menstrual irregularities are rather frequent. In not a few cases the group of premonitory symptoms bears a deceptive resemblance to neurasthenia proper or "nervous prostration," owing to the predominance, for quite a long period, of nervous and bodily debility.

#### THE SOURCES OF DEMENTIA PRECOX.

Authorities differ as to the prime cause of the disease, one group favoring a physical, the other a psychic origin; but wherever its germ, so to speak, may lie, the character of the mental soil in which it takes root and flourishes and the conditions which excite it to full development are well known to the psychiatrist.

One of the profoundest, although more remote, influences in originating dementia precox is the time of life in which the disease prevails,—the period of puberty and adolescence, of growth, development, immaturity. Almost all modern writers on psychiatry, even those who lay special stress on the influence of faulty heredity, are fully alive to the great importance of this critical time of life in fostering mental disease, and in all probability we shall have to seek for the real causes of its origin in the normal physical and mental variations of this period of development.

To appreciate the possibilities of this time of life in the way of mental deterioration we have only to call to mind the unusually rapid growth of the organism in every tissue, the new and powerful activity of all the functions, especially those of nutrition, in the progress toward complete development, and the stamina and often the care that are essential for properly meeting the demands of this revolutionary period. The disturbance of the heretofore tranquil nervous system by the advent of the reproductive functions is a vital change, and the proper adjustment of this part of the organism to the working whole is of far-reaching importance, as the genital activities have a profound effect on the entire system and the developing personality. During adolescence the normal mental condition is not a solidly settled one, and at this time, if ever, should we expect to find pathological disturbance when impressionability, instability of

purpose, variation of mood, excitability, impulsiveness, ambition, independence, and intolerance are most likely to be in full play; when the affections, emotions, and newly awakened sexual feelings and passions are most keen; when reflection and judgment are immature, and, above all, when self-control, which should regulate all, is itself in an imperfect stage and in danger of being unequal to its function. Nothing is more significant of the causative influence of this period than the resemblance of the clinical picture of dementia precox to these ordinary mental elements of normal development which in morbidly exaggerated form constitute the different manifestations and phases of the malady.

When to this developmental factor is added the special mental make-up, sometimes improperly called temperament, of many of these patients, the soil is thoroughly prepared for the growth of the disease. From childhood these individuals are, as a rule, well behaved and easily trained because they shun opposition and struggles from lack of normal vigor and strength of purpose rather than from any inherent virtue. Their tendency to shrink from coping with the world, due to a faulty habit of adjustment, resolves itself into the "shut-in" personality which typifies these cases. This factor, so important in determining the causation and prevention of the disorder, was first recognized by Meyer and August Hoch who found that a large number of cases occurred in persons who, as Hoch puts it, had "no natural tendency to be open and to get into contact with people and things about them, who were reticent and exclusive and could not adapt themselves to situations, who were hard to influence and often sensitive and stubborn, but the latter more in a passive than an active way. They showed little interest in what went on and frequently did not participate in the pleasures, cares and pursuits of those about them; although often sensitive they did not let others know what their mental conflicts were; did not unburden their minds, were shy and had a tendency to live in a world of fancies."

Many of these sensitive natures suffer in silence at their imagined inferiority, always expecting to fail in their efforts to please others or to succeed in their studies or whatever they may undertake. Their pride is easily wounded and they are ever ready to believe themselves slighted. They are excessively over-conscientious, magnify their faults and mistakes, and live in constant fear of what people will think of them. Consequently remorse and shame cause them much suffering except when their troubles are crowded out for the time by everyday duties. Their diffidence and exclusiveness too often pass among their young friends for haughtiness and self-conceit and thereby cause criticism from others—the very thing which they are so anxious to avoid. Submerged and repressed factors which occasionally torment the

adolescent of this type and which the psychoanalyst tries to bring to light and correct are early sexual experiences which are usually exaggerated. The constant and often growing mental conflict caused by the repression of these thoughts is an added strain which is sometimes the precipitating cause of nervous breakdown. Then, too, these youths tend to dwell upon ordinary longings which the normal mind ponders on but puts aside. Hoch found the "shut-in" personality markedly pronounced in 35% and indicated in 16% out of 72 cases of dementia precox.

Another type is the precocious youth, the student who is more or less of a prodigy, a phenomenon. Such subjects are particularly prone to mental breakdown in adolescence owing to the readiness with which their abnormally active minds may be over-stimulated in every direction.

One cannot fail to be impressed also, with the large number of cases of dementia precox which present a family history of mental or nervous disease. Nevertheless many distinguished psychiatrists deny that disease-heredity is a powerful predisposing influence. Kraepelin, the foremost authority on the subject, comes to no definite conclusion on this point, but seems to be opposed to regarding this disorder as a form of degeneracy. He points out that heredity does not appear to be more frequent in dementia precox than in certain other mental diseases and that the best known constitutional disorders, such as hysteria, manic-depressive insanity and psychopathic states do not lead to a mental deterioration but to a periodic recurrence of symptoms with intervals of perfect health which are often long. Statistics on this point are quite diverse.

Badly directed education, moral and mental, may give a wrong turn to the tendencies of the nervous child and thus leave him with little defence against the exciting causes of mental disease when adolescence is reached.

#### PRECIPITATING CAUSES.

The precipitating causes are various, but for the most part are of the nature of exhausting influences—mental and physical strain. These are the most conspicuous and powerful of the exciting causes of the disease. Rapidly-growing youth or girls in the humbler walks of life, apprentices, clerks, train hands, stable boys, mill operatives, domestics—often succumb to the exhausting effects of hard and continuous physical labor combined with long hours, anxiety, little sleep, insufficient food and in consequence disorder of nutrition. Insomnia and lassitude arise and mental breakdown follows, sometimes apparently without the aid of any predisposition to mental disease. Youthful volunteers not inured to military discipline and the hardship and dangers of active service also recruit the ranks of the youthful insane. Social strain in girls

with its attendant factors of malnutrition and fatigue as well as banting may precipitate mental breakdown in predisposed cases. Over-study, of itself rarely productive of mental disorder, causes many a delicate girl or lad of the "shut-in" type to succumb to mental disease when poor circumstances increase the struggle for education. Rapid and excessive growth in height, without corresponding weight and proportionate development, is recognized as abnormal. It is not uncommon in this type of adolescent and may sometimes precede by a little the development of the disease. In these instances there is not sufficient alimentation provided to meet the demand of the growth of the organism *plus* excessive mental and bodily energy.

Self-abuse, if the degrading habit be carried to great excess, and if the child or youth be of the nervous type, is apt to be exhausting and to cause general depression and languor, lessened power of attention, poor memory and dullness; but as ordinarily practised,—and the habit is well-nigh universal in youth,—its results, according to accepted medical teaching, are, as a rule, not so directly disastrous as was formerly believed to be the case, and are more often moral than physical or mental. Contrary to popular belief, masturbation is almost never the cause of mental disease or defect. Melancholy subjects of dementia precox, with delusions of wrongdoing and general worthlessness, often accuse themselves of previous excess in the vicious habit who on recovery admit that they had seldom practised it. Many of its symptoms are purely nervous in character, and are due to shame, anxiety and loss of self-respect, due to a consciousness of a debasing weakness which is universally condemned.

Typhoid and other debilitating diseases occasionally leave the patient in a permanently weakened mental condition culminating in dementia precox. Child-birth and its attendant conditions, with its many disturbing influences, is sometimes the starting point of mental breakdown. Aschaffenburg found 56 cases of dementia precox in 118 cases of so-called "puerperal insanity." Finally, it may be impossible to find any adequate cause for the attack, a small proportion of the cases occurring in the physically strong and apparently stable and socially inclined.

—EX.

No reliable data have thus far been recorded which indicate in which sex the disease is more common. Not a few authors find the disease more prevalent in young men.

#### THE PROGRESS OF THE DISEASE.

There is the greatest variation in the manner in which the disease may progress. In the great majority of cases the first attack may be and usually is more or less pronounced and severe and lasts all the way from three to eight months or a

year, to be succeeded by a remission of symptoms to such an extent that the patient appears to be entirely well and is able, it may be, to live at home. After a time, however, sometimes a year or more, he begins to become easily exhausted in mind and body, sleeplessness sets in and a relapse occurs with deeper dementia though somewhat less acute symptoms. From this attack also he may emerge but, with the mind on a still lower level of strength and rationality, he again relapses and finally the mind permanently succumbs. Others do not have separate attacks but gradually sink into permanent dementia. A large proportion of cases never recover their reason although their physical health becomes and remains good and even excellent.

These temporary recoveries are frequent in dementia precox but substantial recoveries are much more common in other forms of mental disorder. Nevertheless, a certain proportion of dementia precox cases, once estimated by Kraepelin at 13%, appear to get well permanently after one attack and continue ever after to fill their accustomed stations in life to a large extent as well as before, although, as a rule, they never appear entirely the same in the opinions of near relatives in some detail of endurance, judgment or conduct. Other victims of the disease may live on comfortably outside of the hospital but are plainly on a lower mental level than those about them and are regarded as "non-compos." The remainder become irretrievably demented, inactive in mind and body, automatic in their movements and of varying degrees of helplessness, requiring more or less constant personal care. This class of patients, particularly serve to swell the constantly accumulating aggregations of chronic patients in our institutions.

#### EFFECTS OF TREATMENT.

Improved methods have, of late years, unquestionably tended to benefit the condition of these patients and increased the number of recoveries in our custodial state hospitals. Nevertheless, aside from protecting the patients from neglect, injury to themselves and others and the disturbing influences of outside life, securing their physical well-being and providing occupations and occasional diversions (and a vast amount of excellent work is done in these directions), comparatively few curative results are possible for the majority of them where large numbers are cared for together. It is in the treatment of the individual patient that the chances of recovery or improvement are greatest, and the nearer we can approach to this wherever the mental case is under care the better will be the results. By employing resident social workers who interest themselves in the individual patient and his affairs, and increasing the number of nurses, the superintendents of our institutions are now making more progress in this direction.

## THE OUTLOOK.

This is indeed a gloomy picture. It has its counterpart in the condition of sufferers from tuberculosis before the public interest in the subject was awakened and a crusade begun to prevent its ravages. Compare the situation of the consumptive of that day and this. What remarkable progress has resulted in public enlightenment in hygienic measures for the prevention of the disease, in general recognition of its earliest symptoms and in advanced methods of treating the developed disease. At that time it was generally looked upon as an incurable disorder. Once the diagnosis had been made of phthisis, as consumption was then called, the patient was supposed to be doomed. Now recoveries are not only frequent but expected when the case is taken in season, and when relapses occur the intervals of health are prolonged under comfortable conditions by our modern means. Statistics tell the story of the diminution of deaths from this cause of late years. In the early days of the movement no one would have ventured to predict such a general public awakening and such encouraging results.

The situation is to a considerable extent the same as regards mental disease, and the outcome, though less pronounced, will be no less surprising if the mental hygiene movement, both national and state, which is now in its infancy, shall take an equal hold upon the sympathies and interest of the public.

## IMPORTANCE AND MEANS OF PREVENTION.

The chief aim of such organized effort should be the adoption of preventive measures, as they are the main reliance, the anchor to windward against the disease. As a means of combating it, they are infinitely more effective than treatment instituted after it has once gained a foothold; and it is here that the help of parents, teachers and general physicians is indispensable. Familiarity with the remote influences, the precipitating causes and the earliest symptoms of mental deterioration in adolescence is of great value, and not only, be it understood, in warding off the malady but also, by the way, in throwing much light on the traits and trends of the minds of youths and girls who are normal and sound in mind and body. No one has made this plainer than Stanley Hall, our foremost authority on the psychology of adolescence. "One of the missing links," he says, "which are indispensable to full acquaintance with the many forms of precocious mental decay, is the absence of record or available knowledge of the early stages in the development of the disease before cases come to asylums; for of this disease, even more than of many others, it is certain that if all were known, its manifestations would be found to be numerous in proportion as they are mild, and that the vast majority who are slightly impaired by the ferment of this storm and stress

period of life never come under any kind of medical observation. For one I incline to the opinion that just in proportion as these gaps are filled we shall have less need of recourse, with Kraepelin, to toxic and other chemical ease. The paradigms of premature decay," by which he means its parallelisms with the manifestations of the inner and outer life of normal youth, "reveal a body of phenomena of the highest importance for normal genetic psychology, and it should be asserted that no parent, judge, family or army physician, and especially no teacher, should be ignorant of these morbid forms which, in their mild degrees, are so common and the key to so much that is normal, but which are generally concealed to others and often unconscious to self."

Now, mental, like physical, illness, comprises many different "diseases"—between 35 and 40 all told. Some are more curable than others, and some are inevitably hopeless. Dementia precox has been placed, and rightly so, if we have regard only to *past* results, between the two, that is, in the less curable class, but that should not be taken to mean, by any means, that it is not preventable. On the contrary, it is now accepted by those expert in the subject that much of the disease may and should be prevented.

As Campbell of the Johns Hopkins Hospital puts it: "the researches of Kraepelin, Freud and Jung of Germany, and Meyer and Hoch in this country, show that under proper guidance and control many cases of functional nervous disease and insanity are of such a nature as to be manageable and preventable. It is clearly obvious that, of the enormous number of persons who, as a result of hereditary tendencies, are susceptible to nervous and mental breakdown, many could be saved by proper assistance during the developmental stage." Among the preventable conditions which he considers the most hopeful he places dementia precox first. He classes 39% as manageable and preventable.

Unfortunately, the theory of degeneracy has become so deeply ingrained in people's minds that a surprisingly large number still believe that all mental disease is on a par with idioey and imbecility and that it not only cannot be really cured but is impossible of prevention except in some future generation through the admixture of healthy stock. We have far too long lain back content in the belief that it is one of nature's methods of weeding out the unfit, and the mental weakening of this type has been excused for giving rein to his morbid tendencies and his guidance neglected because his father or mother was a criminal and inebriate or insane. It is largely for these reasons that no systematic scheme of prevention has ever been tried for the insane until the recent public instruction in mental hygiene was undertaken.

The practising psychiatrist and the neurologist not infrequently are consulted by patients

with unmistakable symptoms of approaching dementia precox in its very earliest stage, and not a few, under close supervision, change to healthful open-air and congenial but quiet surroundings, suitable companionship and careful following up of their cases, have been restored to rationality, calm of mind and enjoyment of life. Some seem to have recovered; others, if they have not been fully brought up to their original mental level, are at least able to be of some use in the community. In this way occasional cases that seemed doomed to lifelong commitment to a hospital for the insane have been saved. So far as they go, therefore, these results constitute object lessons of the effects of prevention. So, too, the intervals of comparative health occurring between attacks are frequently prolonged when the patient is kept track of by the physician and led to make frequent reports of his progress. In this way relapses may be warded off for a much greater length of time than would have been the case without such supervision. But prevention from this source cannot go far as it is comparatively seldom that such cases reach the physician in time owing to the prevailing ignorance of the danger signals or the refusal of the patient to cooperate. Fortunately, psychopathic hospitals and wards are now receiving more of these early cases, which formerly would have shrunk from going to a state hospital.

Nor should we wait until medical advice seems necessary. It is just here that the help of the parent and teacher may be of the utmost service. They should not only make themselves familiar with the signs of its approach in order to summon medical help in time, but should strive to familiarize themselves with the morbid tendencies that I have endeavored to describe, so that, when possible, they may so direct the lives of their charges that strain and other dangers to young minds predisposed by heredity or temperament to breakdown may be avoided. The "shut-in" type of lad or girl, in which the disease takes root most quickly and frequently, should be generally recognized. It should become a matter of common knowledge that just as a special physical make-up or conformation may betoken tuberculosis so there is in many cases of dementia precox a particular kind of personality which favors its development and calls for precaution in the way of training, environment and mental and physical hygiene. In families of the ignorant and unthinking these danger signals pass unnoticed, but intelligent people may learn the lesson and profit by it, if it be brought to popular knowledge as an accepted scientific fact.

Every endeavor should be made to pierce the shell of secretiveness which envelops these minds, to gain their confidence, and without too much preaching explain to them how needless are their self-depreciation and their fears; how exaggerated are their ideas of

past experiences, especially the sexual, and how mistaken they are as regards their consequences. Girls should have the nature of menstruation and the precautions it necessitates early made plain to them. Boys should be led to look upon occasional seminal losses during sleep as a natural occurrence. Many a frightened youth, for want of a father's foresight and prudence in this direction, has fallen into the hands of quacks, who have worked upon the fears of their victims until they have become morbidly depressed and hypochondriacal. Parents should also see to it that their children are kept from the first in the companionship of other children and take part in the healthy pursuits and pleasures of their mates. They should endeavor to implant normal mental processes in incipient cases and regulate their methods of thought, study, reading, exercise and conduct.

But these means of prevention are often difficult to put into effect in dealing with such inaccessible natures, although they should never be neglected. Fortunately there are other and more tangible means of strengthening the resistive power against morbid tendencies in the direction of bodily nutrition and development and regulation of physical and mental effort in the school, in sports, in the family, in society and in other activities.

To begin with, it is important that special attention should be paid to the accumulation of a reserve fund of bodily nutrition with which to sustain the growing system, especially of the delicate youth, and protect it against physical or mental fatigue. Every possible means should be availed of to prevent such subjects from acquiring the habit of taking irregular, insufficient and unwholesome food. They are liable to develop lasting hypochondriacal fancies which might never arise if they had been trained early in this direction. Louis Starr, writing on the adolescent period, recognizes this danger and believes that bad eating habits lead to many breakdowns of students and cause irritability, anemia, malnutrition and a condition of weakness in which marked fatigue follows such trifling exertion that exercise is precluded and a craving for stimulants engendered. It is essential, therefore, to establish an appropriate diet during puberty. If correction be neglected until after sex development be completed little improvement can be expected. A great many young people are inadequately fed, especially the only child, who is supposed to be delicate. Tracy and Crossdale, in a series of observation tests made during the past year upon 127 typical students at the Philadelphia Normal School for Girls, found that only about one-third of them took three substantial meals a day while the rest depended too largely on hastily-scattered breakfasts and lunches of sweets and pastry and often missed meals altogether. The effect of these habits was easily seen in the general health of the students. There

was a distinct difference in the powers of endurance and vitality of certain girls whose diet was more solid and substantial than the others. Much more does the rapid growth of the young and their enormous and incessant activity of body and mind demand a full and regular supply of nutritious fuel, and they can hardly eat too much. This is especially true of the nervous child who should never be stinted and always encouraged, but never nagged, to eat plenty of all kinds of nutritious food, avoiding perhaps too marked a preference for meats.

The general principles of prevention laid down by Sir Thomas Clouston, the famous Scotch psychiatrist, are practical and to the point. "Build up the bone and fat and muscle by means known to us during the period of growth and development. Make fresh air the breath of life of the young. Develop lower centers rather than higher where there is a bad heredity. Do not cultivate, rather restrain, the imaginative and artistic faculties and sensitiveness and the idealisms generally in cases where such tend to appear too early and too keenly. They will be rooted in a better brain and body bases if they come later. Cultivate and insist upon an orderliness and method in all things. The weakly neurotic are always disorderly, unbusiness-like and unsystematic. Fatness, self-control, and orderliness are the three most important qualities for them to aim at."

I have alluded to the occurrence of attacks of so-called "nervous prostration" during adolescence. They are in reality mild, transient episodes of mental instability and are frequently the starting points of impaired mental stamina whose effects may not come to the surface until later in life under stress of some sort, in the shape of a sharp mental breakdown. It is of importance, therefore, to bear such a possibility in mind in order that the future lives of such individuals may be judiciously ordered and any return of nervous symptoms be promptly met.

Insufficient sleep in the young calls for precautionary measures in the way of less study and more food, fresh air and exercise. Decided loss of flesh with or without any especial mental change should put us on our guard against mental or nervous breakdown in the predisposed and the delicate. Such loss of flesh is not confined to physical disease alone, as is usually supposed. Parents are apt to regard too lightly such indications, and the boy or girl concerned rarely admits mental or bodily tire, in fact does not feel it in most cases, as anaesthesia (absence of physical sensation) of fatigue is not uncommon under these conditions. The adolescent in school or college should be sent home and looked out for without temporizing whenever signs of insomnia, loss of appetite or decided lack of his usual energy and interest in work or sport become evident.

Overstrain in physical effort calls for especial precaution and, while mental and bodily cod-

ding should be discouraged, it should be borne in mind that nervous children become readily exhausted in both directions, and should be guarded so far as possible against pushing exertion to the point of daily fatigue. At the same time plenty of systematic open-air exercise, graduated to the individual's strength, should be encouraged. I have alluded to the necessity for restraint of the mentally precocious boy or girl. The physically precocious also come in for a word of caution. I refer to the very tall, thin, overgrown youths with this mental makeup. If such subjects always could be kept from physical over-exertion and athletic competitions, there would be fewer mental breakdowns.

Over-study is too often singled out as the cause of mental breakdowns; whereas the combination with it of other factors, such as rivalry, the expectations of the student's family, overstimulation of his efforts by the parents, strained circumstances and other sources of anxiety, as well as unhygienic living, is really responsible for the result. Nevertheless, there are not a few nervous children and adolescents, particularly the dull and backward, for whom much mental application is harmful. These subjects should not be forced, and the time spent in study by any boy or girl should never exceed five hours a day, with intervals for rest and exercise. It has been shown that children who study longer than this suffer more illness than those who understudy, and this is more noticeable the younger the scholar, as there is less resisting power.

For shy, sensitive, self-conscious, perhaps over-mothered boys or girls in good circumstances, the routine and associations of a well-selected preparatory school at a distance from home, where the right moral tone, discipline, physical training and an out-of-door life are important features of the school methods, and where they will realize that each of them is but one of many pupils, is an excellent corrective and upbuilder of mental and bodily strength and character. For the more highly nervous this occasionally proves too severe an experience, but it never need be disastrous, and it often happens that the doting and indiscreet parent gives it an insufficient trial. It is generally admitted, according to Stanley Hall, that girls in good boarding schools where evenings, food and regimen are controlled, are in better health than day pupils with social, church and domestic duties and perhaps worries, to which boys are less subject.

Social service work, both professional and amateur, should only be undertaken by the strong and vigorous girl. It calls for constant effort of the most taxing kind, and the anxious-minded, over-conscientious, delicate and determined worker is more than likely to suffer physically and nervously under the strain, besides exposing herself to the danger of mental breakdown. On the other hand, the high pressure of social gaiety when a girl is "coming out" is

only well withstood by the normal, healthy and vigorous girl, and even she is usually pulled down in flesh and spirit when the festivities are over. Late hours, loss of sleep, insufficient nourishment and a feverish unrest are accompaniments of this season, and occasionally have been the precipitating cause of nervous breakdown in the delicate. At all times the cultivation of healthy commonplace activities is the most beneficial course.

Effort at the prevention of mental disease among the poor must perforce be largely confined to the dissemination of simple instruction in mental hygiene through popular lectures, and especially the oversight given to convalescent and presumably recovered sufferers from dementia precox on their discharge from the hospital, through after-care and social service channels. By following up these cases, regulating their home lives and family surroundings, helping them to secure suitable employment and, in general, improving the condition under which the original breakdown occurred, it is sometimes possible to ward off, or at least, delay relapses. For this class this is among the most promising means of prevention. I must in this connection again urge the advantages of psychopathic hospitals with out-patient and social service departments for meeting the disease in the early stages. Nowhere else can the incipient cases among the poor be reached and treated with better prospects of success.

After-care applies with much greater force to cases of dementia precox occurring in the well-to-do for, when once an attack has been experienced, the dread of a relapse causes the more sensible and intelligent to listen to medical advice. They recognize more readily their limitations, and their relatives and their means enable them to escape the sources of fatigue and anxiety to which the poor are subjected.

PAPERS READ AT THE ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY, WEDNESDAY MORNING, JUNE 7, 1916.

### THE COMMUNICABLE DISEASES OF CHILDHOOD.

#### I.

THE RELATION OF THE STATE DEPARTMENT OF HEALTH TO THE COMMUNICABLE DISEASES OF CHILDHOOD.

By ALLAN J. McLAUGHLIN, M.D., Boston.

MODERN health departments have expanded far beyond the field of communicable diseases

and now contemplate in the scope of their work all defects and deviations from the normal, whether due to germs or to other causes.

Teaching personal hygiene and attempting to keep people healthy does not mean that we intend to relax our efforts in the control of epidemic disease. We must hold what we have gained and try to go farther toward the elimination of communicable disease. The fact that typhoid fever has been reduced in Massachusetts to less than 8 deaths per 100,000, and that there are less than 275 deaths annually in Massachusetts from that disease, does not signify that we shall relax our control over water supplies and sewage disposal. Similarly, a continued effort with redoubled energy is necessary further to reduce the death rate for diphtheria, scarlet fever, measles and whooping cough.

In Massachusetts in 1914 the chief factors in our mortality were the following:

Infant mortality.....	9801
Pneumonia.....	5987
Organic heart disease.....	5128
Tuberculosis.....	5061
Cancer.....	3586
Bright's disease.....	3057
Apoplexy.....	2606
Syphilis.....	?
Diphtheria.....	652
Typhoid.....	268
Scarlet fever.....	246
Whooping cough.....	225
Measles.....	189
Influenza.....	129

Measles and whooping cough are much more serious than the figures indicate. A considerable proportion of deaths charged to pneumonia are really chargeable to measles and whooping cough. Important results have been secured in measles by research workers in regard to the period of infectivity and modes of transmission. Education of school teachers and parents in the early signs of this disease promises much in reducing measles still further. We are peculiarly fortunate in having recognized experts like Dr. Place and Dr. Morse discuss these two interesting factors in our death rate.

Our knowledge of scarlet fever has been augmented in the past year by the brilliant researches of Mallory, and the committee is to be congratulated in securing from Dr. Mallory himself a paper upon this subject. Scarlet fever will also be discussed by one of the foremost sanitarians in the United States, Dr. Charles V. Chapin, who, from long experience and ripe judgment, will give us valuable suggestions for the suppression of this disease.

In spite of the enormous reduction in diphtheria during the past two decades, I am not satisfied with the results at present. Considering the high standard of Massachusetts physicians, the free facilities for laboratory diagnosis, the free distribution of antitoxin and material for the Schick test, it is hard to understand that we have over 600 deaths a year from this easily preventable disease. The State Department of Health made an investigation of all

deaths from diphtheria in the past year, hoping to collect data which would show wherein the fault lies.

Is antitoxin given early enough? Is it given in sufficient doses? I am inclined to think that the physicians are not at fault in the bulk of the cases. Our investigation is not complete, but tends to show that in a majority of cases which prove fatal, the doctor is not called until too late.

It is a great privilege to hear an expression of opinion based on vast experience from Dr. Park of New York City, and it will be interesting to hear Dr. Hitchcock discuss diphtheria from the point of view of a district health officer of Massachusetts.

I desire to express my appreciation to the Society for the privilege of opening the session on the subject of the communicable diseases of childhood. I look upon it as an opportunity for improving the efficiency of our work in the state by applying the valuable suggestions which we will receive from the scholarly papers of Dr. Place, Dr. Mallory, Dr. Chapin, Dr. Park, Dr. Morse and Dr. Hitchcock.

## II.

### MEASLES AND THE PUBLIC HEALTH.

BY EDWIN H. PLACE, M.D., BOSTON.

#### OUTLINE.

#### I. Mortality.

- A. American cities—low.
- B. English cities—Liverpool, Glasgow, London.  
Liverpool chart. Measles greater than scarlet fever and diphtheria.
- C. Fluctuation in incidence.  
Boston chart.  
1. Causes: Exhaustion of material, etc.
- D. Fluctuation in mortality.

- E. Boston mortality.  
Contrast with scarlet fever.
- F. Errors in records.  
1. Cases not seen and reported, 10%?  
2. Confusion in diagnosis—toxic rashes and rubella.  
a. Histories of second attacks, etc.  
b. Rubella: distinct disease.  
(1) Diagnosis.  
(a) Incubation.  
(b) Invasion stage.  
(c) Eruption.  
(d) Lymph nodes.  
(e) Koplik spots.  
(f) Severity.  
(g) Immunity.

#### II. Methods of control— isolation, reporting, disinfection and quarantine.

##### A. Isolation.

1. Failure; few escape.  
a. Susceptibility.  
b. Contagiousness early.  
c. Koplik spots.  
(1) Appearance.  
(2) Differentiation.  
Bubbles.  
Food.  
Detritus.  
Thrush.  
Stomatitis.  
Trauma.
- (3) Location.
- (4) Time and duration.

##### B. Disinfection.

1. Early death of virus.
2. Communication to others direct.

##### C. Quarantine.

1. Value.
2. School.

##### D. Results. Postponing of disease.

#### III. Manner of spread.

- A. Period of contagion, carriers, desquamation, late discharges.
- B. Direct contact.
- C. Droplets.
- D. Locus of virus—nose, throat and blood. Animals.
- E. Point of entry.
- F. Characteristics of contagiousness.

#### IV. Measures of management. Importance.

- A. Mortality—due to broncho-pneumonia.
- B. Prevention of pneumonia.  
1. Sunshine, fresh air, free fluids, rest in bed, regulated diet.  
2. Conditions actually found.  
3. Fear of eyes.  
4. Heat treatment.  
5. Draughts.  
6. Local resistance.  
a. Mouth and nose.  
b. Larynx and trachea.
7. Protection from infection.
- C. Limit of influence of these measures.  
1. General condition and nutrition.  
2. Other diseases.
- D. Conclusion.

In American cities, the mortality of measles is relatively low and but little attention is directed to it.

In English cities, on the other hand, as Liverpool, Glasgow and London, and in Paris and Petrograd, the measles mortality has been very high for years.

In Liverpool measles is a more important factor in the death rate than scarlet fever and diphtheria combined. (Chart 1.)

CHART I.

There is a marked fluctuation in the occurrence of measles as shown, for example, by Chart II of measles incidence in Boston.

This fluctuation in incidence is apparently due to a variation in the number of susceptibles. After each epidemic year in a community there follow from one to four, usually one to two, years of low incidence, until a sufficient number of susceptible children have grown up to supply fuel to the spark of contagion.

There is a corresponding fluctuation in the case fatality rate, extensive epidemics being usually associated with a more fatal form of the disease. This is shown in the records of Liverpool, as seen in Chart I. A rise in the total deaths and cases is accompanied, as a rule, by a rise in the case fatality rate.

In Boston the mortality rates, both case fatality and for every 10,000 of the living, have shown no definite downward trend during recent years. This is shown in Charts I, III and IV.

Charts III and IV show Boston's measles and scarlet fever mortality contrasted.

As compared with scarlet fever, it is seen that, for the last ten years, measles has been a greater cause of death than scarlet fever. This is not due to an increase in measles fatality but to a decrease in scarlet fever death rate.

Many errors occur in the records of measles which make figures open to some doubt.

First, many cases of measles are not seen by a physician and are not reported to the health department. This is especially true of mild attacks and of secondary cases in a family. In my histories, which show measles as having occurred previously, nearly 10% were not seen and diagnosed by a physician.

Second, confusion in diagnosis with toxic rashes and rubella, or German measles, is very common. Histories of second and third attacks, and even fourth and fifth attacks, are fairly common, while real second attacks are ex-

CHART II.

sively rare. I have not seen a second attack which I could consider authentic.

Many physicians grant no distinction between measles and rubella, holding that they are forms of the same disease. Others make a false distinction by classing all mild attacks as rubella. Measles and rubella are distinct diseases, and although rubella is usually a much milder disease, some attacks are more severe than mild measles.

Rubella differs from measles as follows:

1. The incubation period is longer, being 14 to 21 days, averaging 17.
2. The period of invasion, or the prodromal

stage, is absent or short, usually being less than one day.

3. The eruption is smaller, more rounded, and more uniform, the spots averaging about 2-3 mm. in diameter. The eruption appears in the same places and order as measles but spreads downward and evolves much faster. The height of the eruption is usually reached on the first or second day and fading is complete by the end of the third day. No pigmentation follows.

4. There is more striking enlargement of the superficial lymph nodes, especially the post-auricular and post-cervicals, although usually all show enlargement. In rubella about 90% show

CHART III.

CHART IV.

post-auricular enlargement to less than 10% in measles.

5. No Koplik spots occur. Early in the course of rubella are often seen small maculopapules on the buccal mucous membranes and soft palate, but there are no granular specks such as distinguish Koplik spots.

6. Rubella is milder and has no complications.

So great is the variation in all these factors in both, however, that differentiation is sometimes excessively difficult and may be impossible. For proof, it may be necessary to depend on immunity evidence. Rubella confers no immunity to measles, and vice versa.

The methods of control which have been in use are isolation, with compulsory reporting, disinfection and quarantine especially as related to the schools.

The results obtained by these methods are practically nothing. There is no evidence that the incidence has been decreased, and there is no more probability of a child reaching adult life without contracting the disease now than generations ago. Very few escape except in very scantily settled communities whose communication with the world is slight. When the disease is introduced in such communities, such as the Faroe Islands, the epidemics are extensive and involve all ages. Most of the immunity in adult life is acquired.

There are several reasons for this failure in measles control. First, there is almost universal susceptibility. My records show that about 90% of young adults have had measles, the remaining 10% being chiefly persons who have forgotten or who have had unrecognized attacks, especially in infancy. Panum found no natural immunity in the Faroe Island epidemic he studied.

Second, measles is highly contagious for several days before the rash and before recognition, even in cases developing in general hospitals. No restrictions are placed, therefore, upon the patients during about half the contagious period. This first half is not only more contagious by far, but the patient does not feel sufficiently ill usually to give up his routine and freely exposes others. Isolation is, therefore, little effective even if many cases did not escape recognition altogether.

Even when diagnosis is made early by means of Koplik spots, communication of the disease to others in contact has usually occurred. Koplik spots, however, are of great value. Recently a nurse on duty in the diphtheria ward reported in the morning with catarrhal symptoms. She had Koplik spots and was isolated. Although the previous day she had been in contact with over 60 patients, many of whom had no history of having had measles, no cases developed. The nurse had a severe attack.

If isolation is to be of value at all, in measles control, it will require the general recognition

of the disease in the catarrhal stage by means of Koplik spots.

In order to see these spots it is essential to have a good light, preferably daylight, and to turn the mucous membrane of the cheek so that the light will reflect from it to the eye. When they are coalescent, the mucous membrane is covered with minute, pin-point, whitish, bluish white or nearly colorless granules, that do not wipe off. When discrete, they stand out more noticeably as whitish specks something like curdled milk, pinhead, or even larger, in size, and with a roseola. They may be few or countless. The appearance is often as though the buccal membrane had been dusted over with very fine white sugar or sand.

Koplik spots must be differentiated from bubbles, food deposits, and detritus, which easily wipe off, and from thrush, other stomatitis, thickening of the mucosa as plaques, and trauma from catching the mucous membrane slightly between the teeth or to rough teeth or tooth-roots. They are best seen on the buccal mucous membrane, but are also found on the palate, pillars, tonsils and nasal mucosa and possibly in the conjunctiva. They occur from one to six days before the rash, usually two to three, fading after two to three days as the rash becomes pronounced. They may fade before the rash appears or appear only as the rash comes out. I have never seen them absent in a true measles case seen throughout the disease, and believe they are as constant as the rash, i.e., practically 100%.

Disinfection is without value in public health work. The virus dies so rapidly, that disinfection adds practically nothing to safety. Beside, the patient has usually already communicated the disease directly to all those likely to come in contact with his surroundings. I have never found evidence clinically of the virus surviving over six hours outside the body, and it usually dies much sooner. If persons who have not been exposed are to be brought in contact with material infected within less than six hours, disinfection may be of value but not otherwise.

Quarantine is of value if it can be applied thoroughly. In fact, it is our only recourse in the management of measles epidemics that is of value. Shut up the contacts or divide them up into small units until the disease burns out.

Schools play no small part in the dissemination of the disease and an epidemic in a school cannot be stopped, as a rule, while the school remains open, until it has exhausted the material. This is in contrast to scarlet fever and diphtheria.

There are many other manners of contact however, and closure of the school, unless home restrictions can be applied, is of very doubtful influence on the prevalence of the disease. To be effective, closure of the school must continue until no susceptible exposed children will return. In Liverpool, where school closure is a common

practice and thought to be of value, the general incidence and mortality does not seem to be altered.

The most that can be expected of these measures is to postpone the disease to a slightly later period of life. Even this is of value as the mortality is much greater, the younger the patient. Barthéz and Sannée gave the following death rates by age:

	PER MILE
1 year.....	92.
2 " .....	53.1
3 " .....	34.4
4 " .....	30.3
5 " .....	24.9
6 " .....	17.5
7-15 years.....	9.6

Liverpool's rate for 1913 shows a similar variation.

The period of contagion is very short, less than two weeks and rarely over seven days. No carriers occur and the desquamation and discharges from nose and ear, etc., after the acute stage, are not contagious, although this is not generally appreciated. Measles is spread chiefly by direct contact and by droplet infection. Recently infected objects such as hands, handkerchiefs, dishes, etc., may spread the disease, but only for a few hours. Measles occurs spontaneously only in human beings and has no natural habitat outside human bodies. Domestic animals are not known to have measles. The virus is present in the blood during the early invasion stage, and just before, as shown by Hektoen and by Anderson and Goldberger. It leaves the body for transmission to others chiefly or solely in the discharges from the nose and throat, and possibly eye. Its point of entry is also the nose and throat.

As measles produces no carriers, it depends for its continuance on the ready transmission by discharges from nose and throat from person to person and on the high susceptibility to the disease. These characteristics explain the great fluctuation in the incidence, the periodic waves that sweep through communities.

With so little evidence of control of the disease and so slight hope under actual living conditions of really restricting the disease, what may be suggested as an outlet for our efforts against measles?

The mortality of measles is essentially the result of *bronchopneumonia*. Enteritis, mastoiditis, meningitis and septicemia, as well as sequelae such as tuberculosis, are occasional causes of death, but fully 90% of the deaths are due to pneumonia.

Chart v shows the percentage fatality of measles in Boston for the last five years arranged by wards. While no ward has solely good or solely bad hygienic conditions, it is evident that those sections of the city in which hygiene in the home is less good have the highest mortality. In contrast to this the diphtheria fatality for the same period shows no such suggestive relationship to general hygiene. The death rate of diphtheria is due largely to specific toxemia, and while greatly increased by ignorance and carelessness, it is not especially affected by hygiene *per se*. (Chart vi.)

Measures of management should thus be based on prevention and treatment of pneumonia, such as securing sunshine, fresh air, free fluids, rest in bed, regulated but sufficient diet, etc.

As a fact, on the contrary, the usual treatment, founded on custom and superstition, consists of dark rooms, stuffy atmosphere, many

CHART V.

CHART VI.

blankets and hot drinks—all factors to reduce resistance and vasomotor tone.

The fear of the eyes which, for generations, has been emphasized by layman and physician alike, should be eradicated with the other superstitions. The only real danger of eye trouble is corneal ulcer which is fostered by uncleanness, trauma and poor hygiene, and the most valuable treatment is cleanliness and hygiene. As von Jurgenson says, we should not wait for the oculist to tell us of the value of light and hygiene. Photophobia is often absent and, when present, may be controlled by shading the eyes or with goggles while the patient has the advantage of fresh air and sunshine in his room.

The heat treatment and sweating for the purpose of keeping out the rash is a relic of barbarism and the result of false reasoning. It should have disappeared with universal blood-letting and purging.

The much dreaded "striking in" of the rash is not seen in patients treated under modern

hygienic conditions. Of course the rash does not "strike in." Simply the blood to the skin is withdrawn to the splanchnic area due to vasomotor paralysis, and the resulting blanching of the skin causes the rash to fade. The heat treatment, while of value at times in the presence of such shock, is of no value in forestalling it in these toxic states. In fact it is likely to reduce vasomotor tone.

Fresh air and draughts are sedulously avoided. In my opinion draughts do no harm, although chilling the patient so that the extremities become and remain cold is harmful whether from a draught or not. So long as patients are warm and comfortable, the out door treatment is the best for measles.

Beside these attentions directed toward general resistance the local resistance of the mucous membranes should be favored. Cleansing of the mouth, the use of oily protective sprays, plain or with camphor and thymol and eucalyptol for the nose if obstructed, and the free intake of

CHART VII.

water, may all have some bearing on mucous membrane infection. It is doubtful if inhalations of any kind are of great value in the local resistance of the mucous membrane of the lungs, but they may be of value for infections of the larynx and trachea. Relief from the harrowing cough is essential, and expectorants (of which water is the essential) and codeine are often necessary to favor sleep and avoid local trauma from constant coughing.

Protection of measles patients from other infections like the common colds and diphtheria is especially important. It is probable that the organisms producing pneumonia are usually present on the mucosa in measles and are not imported from other patients who are already ill with pulmonary complications. E. W. Goodall reported that of 220 consecutive cases of measles admitted to the Eastern Hospital, Lon-

don, 19.5% had pneumonia on admission; while of 177 cases admitted, without complications, only 6.3% developed pneumonia. I have failed also to find any definite connection between the cases developing pneumonia after admission and cases which already had pulmonary infection. It is worth while, however, avoiding even the risk.

These measures will not eradicate, of course, the death rate of measles or pneumonia. The general condition of the patient, his vitality and nutrition, as well as absence or presence of other diseases, are important factors in the mortality when measles develops. In good homes and in healthy children in good hygienic surroundings the mortality is very low; while in weak and ill children it is very high.

Comby gives the following figures for hospital and asylum cases:

## Hospice des Enfants Assistés:

5 years 1575 cases 728 deaths 46.22%

## Hôpital des Enfants Malades:

7 years 2585 cases 1045 deaths 40.15%

## Hôpital Trousseau:

5 years 907 cases 227 deaths 25.02%

In contrast to this are the figures of the Newton Board of Health.

I believe that a definite decrease in mortality may be secured by the application more generally of the principles of hygiene to patients who become ill with measles. Occurring in each generation, the disease is especially subject to the handing down of home ideas of treatment. It is for the medical profession to substitute for the irrational and often harmful ideas of management a sensible, rational and scientific handling of measles.

## III.

## THE ETIOLOGY OF SCARLET FEVER.

BY F. B. MALLORY, M.D., BOSTON.

THE primary lesion of scarlet fever is located in the respiratory tract, starting usually in or around the tonsils. In severe cases it may extend to the naso-pharynx, to the larynx, trachea and bronchi, or to the esophagus. The lesion consists of necrosis and inflammation. It may affect only the surface epithelium, but often invades also the underlying tissues. The exudation consists of serum and polymorphonuclear leucocytes. Fibrin may be absent or formed in moderate amount. The lesions may appear from the beginning as erosions or as membrane-formations. In the pharynx erosions are often visible even in mild cases. In severe infections membrane formation may occur in the larynx, trachea, and bronchi, but it is rarely or never so dense or adherent as in diphtheria.

Study of the lesions of scarlet fever shows the presence in them of a delicate gram-positive bacillus in large numbers. A brief statement of what Dr. E. M. Medlar and I have found up to the present time is appended; also three plates of illustrations. The subject was presented to the Society in the form of a lantern-slide demonstration, but a connected account of our findings seems more proper for publication.

Microscopic examination of the tissues from a child dying from scarlet fever on the second day following the appearance of the skin eruption shows large and small masses of gram-positive bacilli in some of the crypts of the tonsils. The bacilli lie in the upper portion of the fibrino-purulent exudation covering the walls of the crypts, from which the lining epithelium has disappeared. Streptococci are fairly numerous all through the exudation, occasionally in the underlying tissues, and also abundantly in the free pus present in the lumina of the crypts.

Clumps of similar bacilli occur in the exudation on the surface of the tonsils. In addition, masses of these bacilli are present in practically pure culture in slight depressions and erosions in the squamous epithelium covering the tonsils, the pillars of the fauces, the soft palate, includ-

PLATE I. FIG. 1.—Trachea (10,20); moderate membrane formation with masses of bacilli in the upper portion of it. X200.

FIG. 4.—Lung (10,20); masses of bacilli in alveolar spaces; exudation of serum, polymorphonuclear leucocytes, and a little fibrin. X200.

FIG. 2.—Pharynx (05,109); masses of bacilli on surface of lesion. X200.

PLATE III. FIG. 5.—LARVIX (05,109); masses of bacilli along the surface of a thin membrane. X200.

PLATE II. FIG. 3.—Bronchiole (10,20); clumps of bacilli along epithelial surface; exudation of serum and polymorphonuclear leucocytes. X200.

FIG. 6.—Same as Fig. 5. X1000.

ing the uvula, and the root of the tongue. The bacilli grow in between the epithelial cells, killing them and causing an exudation of polymorphonuclear leucocytes. Little or no fibrin is found.

In the trachea the epithelium has disappeared. The surface in places is covered with a thin layer of fibrin and leucocytes. Along the surface and in the upper part of this exudation are masses of bacilli similar to those present in the epithelial covering of the soft palate. Where the exudation has been detached from the wall,

the bare basement membrane shows the same bacilli scattered along it in small numbers.

In the lung is a well-marked broncho-pneumonia due to masses of bacilli like those in the trachea, and occurring apparently in pure culture. Some of the bronchioles and alveoli are completely filled with the organisms. The inflammatory exudation consists almost entirely of serum and polymorphonuclear leucocytes. But little fibrin has been formed.

In a second early case the tonsils show considerable necrosis and ulceration. In the exudation are many streptococci. Along the surface of the exudation in the crypts are small masses of organisms which stain irregularly and are evidently disintegrating. Their exact structure cannot be determined. On the surface of

the pharynx and larynx are lesions similar to those in the first case, but more extensive. In places the organisms form a continuous layer. More fibrin is present in the exudation, and occasional clumps of cocci are found.

Smears made from swabs thrust deeply into the crypts of the tonsils in three early cases of scarlet fever (from ten to forty-eight hours after the appearance of the eruption) showed small and occasionally large masses of gram-positive bacilli similar to those described above in the lesions found at post-mortem examination. In two patients without tonsils, smears made from the pillars of the fauces and from the soft palate showed similar bacilli in small clumps. Curettings of erosions on the soft palate of one of these patients showed masses of the same bacilli. In smears made only from the surface of the tonsils of two cases the findings are doubtful.

Cultures of a bacillus resembling morphologically and in staining reactions that found in the post-mortem tissues, and in the smears from the tonsils and soft palate, have been obtained in five instances, four times from the crypts of the tonsils and once, when the tonsils were absent, from the soft palate.

The organism is a strongly gram-positive bacillus (decidedly more so than the diphtheria bacillus). It stains well with ordinary dyes and shows a tendency to irregularity of staining in lightly stained preparations. This irregularity of stain is also noted in too strongly decolorized gram preparations. No polar bodies are present.

In culture the bacillus is slightly smaller than the diphtheria bacillus, and varies from coccus-like to large bacillary forms. The average-sized bacillus is 1 to 3 micra in length by .5 to .7 micron in diameter. It is broadest in the middle and tapers slightly toward the ends, which are rounded. Ordinarily in smears from growth on solid media the bacilli are in masses arranged similarly to diphtheria bacilli. Pairs and short chains of bacilli are common, while occasionally, and more constantly in the water of condensation, long chains are found.

The bacilli in tissues and in direct smears from scarlet fever cases are slightly larger than the organisms in culture, but otherwise resemble them. In some instances there is a greater tendency toward irregularity of stain than in cultures.

The organisms isolated are facultative aerobes. They grow best anaerobically upon serum-glycerin (3%) dextrose (5%) agar. Less abundant growth upon other media occurs.

The colonies attain the size of .5 to 1 millimeter in diameter in twenty-four hours at 37° C., and after that do not greatly enlarge. By direct illumination they are opalescent with an opaque refractive center more noticeable in the larger and older colonies. Upon micro-

scopic examination they are finely granular. Their edge is entire or slightly undulate.

It seems reasonable to infer from these observations that scarlet fever may be due to a strongly gram-positive bacillus (*B. scarlatinae*) which is less virulent than the diphtheria bacillus, but which infects practically the same localities, and in severe cases may extend in the same way to adjoining tissues, especially the larynx, trachea, and lungs. The toxin causes necrosis and desquamation of the covering epithelium and leads to an exudation of serum and polymorphonuclear leucocytes. Fibrin formation is usually absent or slight. On this account the primary gross lesions are inconspicuous and easily overlooked. There is usually little membrane formation to call attention, as in diphtheria, to the lesions.

The bacillus of scarlet fever usually dies out quickly in the lesions, so that after the second or third day following the eruption, it is often difficult or impossible to demonstrate it, but it opens the way for streptococcus invasion and seems to favor its growth.

#### IV.

#### SCARLET FEVER.\*

By CHARLES V. CHAPIN, M.D., PROVIDENCE, R. I.

THE attempt to control an infectious disease may do two things. It may reduce the incidence of the disease, as has been so signally accomplished in yellow fever, typhoid fever and malaria; or it may reduce the case fatality, as has been done by the use of sera in diphtheria and cerebrospinal meningitis.

Although there is at times much difficulty in interpreting vital statistics, yet it is necessary to make an ultimate appeal to statistics to determine whether measures of control are effective. The mortality figures for scarlet fever are most encouraging. Thus in Boston the mortality from this disease in the five years 1855-59 was 142 per 100,000 living, while in the five years 1906-1910 it was only 9. In Providence it fell from 124 in the decade 1856-1865 to 15 in the decade 1906-15. A similar reduction is noted in many other American and European cities, particularly in England. To what is it due? Unlike the reduction in diphtheria mortality, it is probably not due to better treatment. It may be due, wholly or in part, to a diminished virulence. It is well known that scarlet fever varies greatly in this respect. Has there been a change in Boston or Providence during the last sixty or seventy years sufficient to account for the lessened mortality? This is not easy to determine. During the thirty-two years during which there has been notification of cases in Providence, the apparent case fatality has varied considerably. It was decidedly high during the first few years, ranging from

\* Read at meeting.

about 10 to 22%. That this was, to a considerable extent, due to defective notification is almost certain, as was the high case fatality of typhoid fever and diphtheria at the same time. The memory of physicians over such long periods is not trustworthy. The only other criterion of virulence suggested is the index of plural deaths. The frequency with which more than one death occurs in a family ought to indicate the virulence of a disease. At considerable labor I had worked out the ratio of plural deaths in scarlet fever for a number of years, and found, where the case fatality was known to be high the number of plural deaths was high. Selecting ten years with an average case fatality of 2.62 the ratio of plural deaths was 5.3, while in ten years, with an average case fatality of 8.5, the ratio of plural deaths was 11.2. In 1906-7 a much more severe type of scarlet fever appeared, with a case fatality of 12%. The ratio of plural deaths to total deaths in these two years was 12. It would thus appear that the ratio of plural deaths is a rough indication of the severity of the disease. Turning now to the first decade of death registration, 1856-1865, it is found that the average ratio of plural deaths was about 9, or nearly twice as great as in the years when the case fatality was 2.6. It seems highly probable that half a century ago the disease was at least three or four times as virulent as at the present time, but as the deaths were from ten to fifteen times as numerous it is a fair inference that the disease is not only milder, but far less prevalent today than it was fifty years ago. This diminished prevalence is probably due in part to isolation and is partly because a severe type of the disease is apparently more infectious than a mild type. On the whole, it may be inferred that isolation has to a considerable extent diminished the incidence of the disease, but that a decreased virulence is also largely responsible for the greatly lowered death rate. Another indication of the effect of isolation is seen in the curve of scarlet fever mortality. In many cities, before isolation was enforced, the disease occurred in sharp outbreaks, four or five years apart, much as measles occur now, though at slightly longer intervals than measles. After notification and isolation the curve flattens out and the epidemic peaks are much lower, thus indicating a real control of the disease.

It is stated by English observers that the age of attack has been postponed, which is desirable in itself, as the fatality is far less after the second year, and also indicates that restrictive measures have really reduced the incidence of the disease.

I am also inclined to think that isolation has been an important factor in reducing the severity of the disease. If a disease tends at all to breed true, that is, if severe cases follow severe and mild follow mild, isolation, as generally

carried out, must lower the virulence. The severe cases are sure to be recognized and are isolated, so that they have less chance of perpetuating their strain than have the mild cases, which so often fail of recognition. Scarlet fever does breed true to some extent, for we find a mild type often prevailing for years in a locality. On the other hand, although the mild type quite generally prevails at the present time, more or less severe outbreaks occur. Thus in Providence for about four or five months in 1906-7 there was such an outbreak, with a case fatality of 16 or more. Similar outbreaks are from time to time noted elsewhere, and the type is carried from one community to another. At present these outbreaks are not very numerous, and they seem usually to be checked, as one would naturally expect that they would be. A similar phenomenon is noted in smallpox, a very mild type of which has persisted for about twenty years. The severe type has been introduced from abroad many times, but has always been stamped out, often very promptly. If this theory is correct, isolation accomplishes as much, and perhaps more, by decreasing the severity of the disease, as it does by decreasing its prevalence.

The great reduction in the mortality in Boston began in 1877, two years after systematic isolation was inaugurated, and in Providence in 1889, three years after isolation was inaugurated. So also the marked decrease in the number of deaths in English cities is, in a way, coincident with the application of methods of isolation. It is to be noted that, while there has been some irregular diminution in the death rate of late years, it has not been nearly as marked as it was at the beginning of public health activities against the disease. Thus in Providence during the last twenty years the rates for the five-year periods have been 9, 11, 21 and 9. In Boston they were 20, 15, 10 and 9. In all the registration cities of the United States the rate fell from 12.8 in the five years 1900-1905 to about 11.9 for the five years 1909-13. The retardation in the decrease has taken place in the face of a slowly-improving notification, better isolation and increasing hospitalization.

The most effective means of isolating a case of contagious disease is to put it in a hospital. This view induced the English to attempt to stamp out this disease, or reduce it to a minimum, by the hospitalization of as many cases as possible. This began to be urged thirty-five or forty years ago, when the high mortality of the disease was a serious menace. Many large hospitals were built, and in a number of cities the hospitalization of a large proportion of reported cases has been accomplished, but with very disappointing results. The disease is far from exterminated. There are more cases in London than in New York, more in Liverpool than in Boston, more in Leicester than in Provi-

dence, though hospitalization is far less complete in the American cities.

It thus appears that the control of scarlet fever by the usual methods of home isolation and hospitalization is disappointing. The disease is still very prevalent and, while decreasing, the decrease is not rapid. In England, where in many cities 90% of the cases are removed to a hospital, they are questioning the wisdom of such an expensive method of isolation, which has so little influence on the prevalence of the disease.

In this country health officers for the most part thoughtlessly follow routine methods of control and hope, by urging better reporting by physicians, and perhaps more stringent isolation, further to reduce the disease. It is generally agreed that the chief reason for the failure of isolation is the existence of so many missed cases and carriers. Many believe that the former are more common and much more important than the latter. It is alleged that to control the disease it is necessary for the health officer to go out and search for the mild cases, which either have not been seen by a physician, or have not been recognized by him. Dr. Hill, former epidemiologist of the Minnesota State Board of Health, and Dr. Chesley, his successor, have been most successful in developing this investigation of sources of infection. In a recent article, Dr. Chesley<sup>1</sup> has given an excellent description of the control of an outbreak in a town of some 5000 inhabitants, in which there had been many mild cases, which were generally believed by the physicians, as well as by the laity, to be German measles. Every child in school was carefully examined, all absentees looked up, all reported cases investigated, and all with whom they had been in contact during the period of incubation, sought for and examined. All susceptibles who had been in contact with the sick were kept under observation. The examination of all school children and of all who are sick at home, and the working out from every frank case which can be discovered, both to find missed sources, and to prevent danger of cases developing in contacts, are the essentials. Dr. Chesley does not favor too strict isolation of the cases and deprecates unnecessary hardships for well wage-earners as tending to encourage concealment. It is stated that many scores of outbreaks of scarlet fever in Minnesota have been cut short by these methods. Doubtless such an intensive search for missed cases is best suited to small communities, especially those with a homogeneous and English-speaking population. Doubtless, also, it is easier for some one with authority from outside, like a state health officer, to step in and take charge, than it is for the local health official to undertake such work. Nevertheless, there is no doubt that more intensive work of this kind in ferreting out sources of infection, especially

in the beginning of an outbreak and in small communities, would very materially reduce the prevalence of scarlet fever in such communities.

Even in the large cities probably something more might be done by a more diligent search for missed cases, but it can scarcely be hoped to lower materially the incidence of the disease in this way. Imagine how futile it would be, in a crowded Polish or Italian quarter of Boston or Providence, to attempt to find and follow up all the persons with whom a seven-year-old boy had come in contact during the preceding week. It is to be feared that the disease cannot materially be lowered in this way.

Though striking results may not be obtained in every community by isolation, yet, even ordinary routine methods of control have great value. By them the virulence of the disease is lowered, its prevalence is kept down and slowly diminished, and if abandoned there would probably soon be a reversion to conditions of fifty years ago. What we should strive for is the isolation of more cases, not more isolation of the cases. To determine the essentials of isolation, reference must be had to what is known about the mode of infection. This knowledge is considerable in view of the fact that nothing has hitherto been known of the causative organisms of the disease.

The incubation period is variable. Most cases develop within three or four days, though a few may be delayed for two, or perhaps three, weeks. A week is a very practical period for the supervision of contacts.

Scarlet fever is certainly infectious as soon as the first throat symptoms appear. The infectivity is at its height during the first days of the disease. In uncomplicated mild cases it soon begins to diminish. Many think that a large proportion of mild cases of scarlet fever are free from infection by the end of the third week; doubtless, at times, even earlier. Unfortunately in many cases the infectivity is greatly prolonged. The experience of the London hospitals shows that five, or six, per cent. of the cases are infectious for over six weeks. A few cases remain infectious for months. There seems to be a correlation between the complications and the duration of infectivity.

The infective material is certainly found in the throat secretions. The pathological condition also extends to the nose, as in diphtheria, giving rise to a nasal discharge, which is also infectious, as in the latter disease. So also is the aural discharge, but this is not so important. Nothing is known about the infectivity of the urine. There is a large amount of evidence that the exfoliated epidermis is not infectious. This can safely be disregarded in the release of patients. Patients should be isolated as long as there is any inflammation of the throat, any nasal, or aural, discharge. The latter may, however, at times be disregarded, especially if the ear is to receive proper treatment. The re

<sup>1</sup> Chesley: *Am. Jour. Pub. Health*, 1916, vi, 234.

removal of tonsils and adenoids, if the operation is indicated, is believed by many to shorten the period of infectivity. After every precaution is taken, it will be found that a certain number of cases, apparently entirely normal, are yet infectious, that is, they are true convalescent carriers. For a mild, uncomplicated type of the disease, probably four weeks is a reasonable period of isolation. When the disease is more virulent, and there are many cases with complications, it is doubtless safer to prolong it a week or two.

The disease frequently presents a very mild type. There are numerous cases with a slight sore throat, a very fleeting eruption and scarcely any fever. Sometimes there is no eruption. There are doubtless true carriers, that is, persons infected but presenting no symptoms whatever; but our knowledge of these is limited. There is evidence that the number of mild, unrecognized cases is large, perhaps equal in number to the reported cases.

Scarlet fever is not especially contagious. It is less so than measles, whooping cough, chicken pox, or smallpox. It is spread almost exclusively by contact with the fresh secretions of the throat and nose. It is rarely, if ever, airborne. Infection by fomites, as the term is ordinarily understood, is negligible. Infection almost never passes from one family to another in the same dwelling unless the families mingle.

Isolation of the case in the family is not very difficult. Too much should not be attempted. The most important matters only should be insisted on, otherwise complexity of detail will result in neglect. The patient, of course, must be kept in one room. One person only should act as nurse. A wrapper, which is kept in the room, is to be worn if much is to be done about the patient. On leaving the patient, the hands must always be washed in hot soap and water and well rinsed, preferably in running water. As few dishes as possible should be used, and these should be scalded and washed by themselves. Soiled linen should be placed in a wash-boiler or dishpan kept in the room, and should afterwards be boiled. It is preferable to have these procedures demonstrated by a nurse. It seems likely that frequent visits by a nurse during the course of the disease is the most effective means of securing proper care of the case and enforcement of rules. It is better than visits by doctors, or policemen, though the latter are sometimes needed.

Children in the family should not go to school. Those who are susceptible should be well isolated for a week. Later they may be allowed more freedom. Adults should not be seriously restricted. Milkmen and other food handlers should move away, also those who come much in contact with children. Laborers, mechanics, clerks, and indeed most wage-earners, need not be kept from their occupation.

The most expensive means of isolation is the

hospital, yet it is a necessity. There are a considerable number of persons who are so ignorant or careless, or who live under such bad conditions, that reasonable isolation at home cannot be secured. While the proportion of wage-earners who should be kept from work is not large, keepers of small stores connected with the house, peddlers of fruit, candy and ice cream, messengers and others, are apt to live so that home isolation is not practicable, and their loss of occupation would be a serious economic disaster. It is by no means necessary to attempt to provide hospital accommodations for from 90 to 95% of the cases, as is done in England. Probably if 40 or 50% of the cases most needing it, could be removed to a hospital, the full value of the latter would be secured.

## V.

### REPORT ON THE FATAL CASES OF DIPHTHERIA OCCURRING IN THE CONNECTICUT VALLEY<sup>1</sup> HEALTH DISTRICT IN MASSACHUSETTS DURING 1914.

BY JOHN S. HITCHCOCK, M.D., NORTHAMPTON, MASS.

DURING this past winter and spring the State District Health Officers of Massachusetts have been looking up the 1914 fatalities from diphtheria. The mortality from this disease was relatively high and there had been no material decline in it for several years prior to 1915, therefore it seemed well worth while to have the details concerning it on file. Because of the lapse of time and movements of people, this must be permanently incomplete, but we have learned some valuable facts. This paper is a preliminary report of this survey and covers only the facts learned by me in the Connecticut Valley District.

This District includes 1156 square miles, and contains 334,700 inhabitants, 213,684 of whom live in the four cities and 121,016 in the forty-three towns. The physical conditions vary from hill towns with a large acreage per person, to cities with densely congested districts; sanitary conditions, from crowded, filthy cabins in the country and tenement-house life in the cities, to the finest of country estates and the most modern of city houses; the character of the population, from the super-educated person of means and leisure, to the dull, non-English-speaking, recent immigrant.

From this District, in 1914, there were reported 598 cases of diphtheria, with 73 deaths, a case mortality of 12.2%. During this same year the case mortality of the State at large was 8.07%, and of the United States Registration Area 10.96%. These cases were located in the towns and cities along the river bottoms; none of the high hill towns reported a case, although three of them sent in specimens for examination.

Postal communication between many parts of

this District and Boston depends for promptness on catching certain mail trains, and renders the general use of the State Laboratory for diagnostic purposes unsatisfactory. There are several private and municipal laboratories that serve the section well. During 1914 the following diagnostic examinations were made:

By the State laboratory .....	192
By municipal and private laboratories .....	2064
	<hr/> 2256

A total of 3.78 times as many specimens as there were positive cases reported.

This examination of more than ten times as many specimens by local laboratories as were examined by the State Department laboratory is a clear showing of the inconvenience of the latter for use by the people in the western part of the State, and is a strong argument for the establishment of a branch of that laboratory in that section.

Among the poorer people here, just as elsewhere, a doctor's fee is not a light matter, while a sore throat in some member of the family is a common, almost constant, visitor, and one to whom home remedies are applied too confidently. As a consequence we find that among these 73 cases the doctor was called on the first day in 15, on the second day in 12, on the third day in 7; total during the first three days of 34, or 46.5% of cases, leaving 39 cases, or 53.5%, in which he was not called until the fourth day or later. Twenty-seven of the 73 cases, or 36.9%, died on or before the fifth day of the disease. This shows how often the doctor had only one day to work in.

Since diphtheria antitoxin is our standard remedy for the disease, we are interested in the record of its use here.

52 cases, antitoxin was given and the amount recorded
5 cases, antitoxin given, amount not recorded.
15 cases, no antitoxin given.
1 case, no facts learned.

In the 52 cases where details were recorded,

Total amount given.....	781,500 units
Average amount given.....	15,000 "
Largest total to one case.....	150,000 "
Smallest total to one case.....	1,500 "
Average initial dose.....	6,800 "
Largest initial dose.....	50,000 "
Smallest initial dose.....	1,000 "

Perhaps the most striking fact brought out by these records is, that, while the average amount used was 15,000 units and the average initial dose 6800 units, 26 cases, or 35%, received a total of 6000 units or less; and 23 cases, or 31%, received an initial dose of 3000 units or less, and the majority of these 73 cases were obviously in a serious condition when first seen.

Antitoxin was not given in 15 cases because

- 2 cases were dead when the doctor arrived,
- 2 cases died while antitoxin was being procured,
- 7 cases were moribund and the doctor thought it useless,
- 4 cases the family refused to allow its use.

If diphtheria cases were met with more frequently in general practice all physicians would carry a supply of antitoxin in their medicine cases; having to procure it not only delays its administration, but focuses the attention of the family on the procedure. They believe it must be an extraordinarily powerful and little used remedy, hence dangerous to the child, and opposition to its use is at once stirred up, especially among ignorant people. If, after its use, in spite of opposition, the child dies, the family is unshakably convinced that the death was due to the remedy, not to the disease.

#### TYPE OF THE DISEASE.

Pharyngeal only.....	32 cases, 43.7%
Laryngeal, or with larynx involved.....	41 cases, 56.3%

Of the laryngeal cases,

- 7 were intubated.
- 1 was tracheostomized.
- 4 died while being intubated.
- 1 intubation was refused.

#### DEFINITE CAUSES OF DEATH.

47 (64.5%)—Toxemia.
11 (15.0%)—Heart complications.
(7 myocarditis after apparent improvement.)
(4 sudden heart failure on exertion.)
7 (9.5%)—Suffocation.
3—Sepsis from co-existent infection.
2—General paralysis after six weeks.
1—Bronchopneumonia (after expulsion of tube).
1—Nasal hemorrhage (uncontrollable).
1—No record obtainable.
<hr/> 73

The record of the seven cases in which no antitoxin was given because the doctor in charge thought it was too late to be of any use, together with the statements made by physicians during the course of this survey, has compelled the writer to believe that many of us hesitate to use antitoxin to the best advantage because we have not a clear knowledge of its nature and action.

When I studied medicine, diphtheria antitoxin was unknown. When it was first introduced the common belief was that its action was directly bactericidal. That first learned impression stays in the front of my mind despite the fact that I know better, and it requires a definite mental effort for me to retire this impression behind the facts as we now see them. The same is evidently true of many of my confrères. Therefore, for the benefit of the older men, and at the risk of being tedious to the younger men, I propose to rehearse again the nature of this "antitoxin" and how it works.

To begin with, it has no direct bactericidal action whatever on the bacilli. It does two things: It neutralizes the poisons, the toxins, that the bacilli produce, and it takes away from the bacilli some of their unusually effective power to resist the attacks of our phagocytic cells. It neutralizes these poisons very much as an alkali neutralizes an acid, much as alcohol stops the corrosive action of carbolic, and like them, it does not repair any damage that may have already been done. It reduces the power of resistance to phagocytes very much as taking away the kick from a mule would reduce his power of resisting his enemies.

The antitoxic elements in the product we call "antitoxin" have no direct effects that are dangerous to human life. There is, however, a very real, though not a common danger in the use of this product, "antitoxin," which depends on the blood serum that is in it. The introduction of foreign protein into the blood of certain susceptible individuals may cause an explosion of sudden, alarming, even fatal symptoms. This series of symptoms is known as "anaphylaxis." I use the term with fear and trembling, it is so vague and varied in its meanings as used by different men. It seems sufficient for me to know in connection with diphtheria antitoxin that, in persons who suffer from "horse asthma" or "horse hay fever," that is, asthma or hay fever which is brought on by the smell of a horse, a dose of antitoxin may be immediately followed by sudden death, and, that in certain other persons with similar tendencies who have received one dose without showing any bad results, if a sufficient amount of time is allowed to elapse, the administration of a second dose, even a small one, may be followed by the same fatal symptoms.

Aside from these two rare conditions,—really phases of the same condition,—the use of antitoxin, even in large doses, is absolutely without danger to the life of the individual. Eczemas and urticarias are fairly frequently caused by it, but these, while at times distressing, are trivial effects when compared with the life-saving properties of the remedy.

The first of the phases of this actual danger may be guarded against by questioning the parents or friends as to the presence of this "horse asthma." If the patient is a sufferer from it, has a mild attack of diphtheria and you can probably carry it through along old lines of treatment, do so. If the case is severe and you need antitoxin, inject four or five drops and watch for an hour. If no untoward symptoms develop in that time, you can go ahead with the full dose in safety.

The second phase of actual danger is to be met by giving a sufficiently large initial dose to avoid having to repeat it.

In order to neutralize the poison of the bacilli the antitoxin must get into contact with it. If given subcutaneously, it is rather slowly

absorbed and its good effects do not appear for some hours. If the condition of the patient calls for quick action, it should be given intravenously. By this method neutralization of the toxins is accomplished far more quickly and with a much smaller dose of antitoxin than if the subcutaneous injection is used. Take those seven cases in the list reported in which the remedy was not given because the doctors thought them too far gone to be helped—it is well within the bounds of probability that some of them might have been saved by the intravenous use of the remedy. No patient while still alive is too far gone to be beyond the possibility of help from an intravenous dose.

An incident connected with this inquiry illustrates this as well as other points. A physician, when asked what killed a certain patient, said that he did, because he did not insist on the use of antitoxin before a positive laboratory report could be obtained. By reason of overgrowth, this was not secured for five days. The family then withdrew their prohibition and the antitoxin was given but without success. Within two weeks after my visit he was called as a consultant in a moribund case. In telling me about it later, he stated that, except for our previous talk, he would have agreed that it was of no use to do anything for this child, but that, since he did not care to tell me again that he had not done everything possible, he put 20,000 units into a vein and the child recovered. That very large dose neutralized the poison effectively and just in time.

Another point brought out is that the doctor assumed the responsibility of the death of the first child on the ground that he had lost time while waiting for the laboratory findings. As a matter of fact, he had taken two specimens daily in order to confirm his clinical diagnosis as soon as possible.

Another point brought out is that he had the courage to use the large dose of 20,000 units intravenously in this dire emergency.

The moral of all this is: Use antitoxin early and freely without waiting for confirmation of your clinical diagnosis even if it be only a tentative one. I agree heartily with the Boston Board of Health which suggests that any case that is clinically suspicious enough to warrant taking a culture for diagnosis is suspicious enough to receive antitoxin without waiting to hear from that culture. Time counts for so much in the efficacy of treatment for diphtheria that not a moment should be lost through indecision. In this series of 73 cases, the doctor's first visit was not made until the fourth day or later in 39, or 53.5% of the cases, while 27 cases, or 36.9% died on or before the fifth day. It seems fair to assume that the intravenous administration of antitoxin in large doses when these critical cases were first seen would probably have saved a number of these lives. Toxaemia was the cause of death in 64.5% of all these cases

and toxæmia is the very condition that antitoxin most surely controls. The degree of control will depend on the amount used and on the time and method of its administration as adjusted to the needs of the individual case.

The important factor of delay in calling the doctor is closely connected with the financial standing of the families, 91.8% of these deaths occurring in families in poor circumstances. The doctor's fee is no small item to them and he is not called for a sore throat unless it is a pretty bad one, consequently, sore throats treated by home remedies are so common that often neither the patient nor the mother connects a sore throat with other manifestations for which a doctor may be called in. In my opinion a doctor who fails to inspect the throat of every child under five years whom he is called to visit for any purpose or symptom is coming close to malpractice. No matter what the illness, the throat should be examined as a matter of routine. Many an unsuspected diphtheria has been unearthed in this way.

Heart complications rank second in our causes of death, being responsible for 15%. Of the 11 heart cases, seven died from myocarditis which appeared after the acute symptoms were over and convalescence was apparently established. In four of these seven the myocardial symptoms followed grave, unauthorized errors in diet, with resultant diarrhea and vomiting. Four of the heart cases died of sudden heart failure following muscular exertion: for example, one of them sat up quickly in bed to say "Hello!" to the nurse and dropped back dead. These heart cases should remind us that the disease is a serious one even when apparently mild, and that the period of convalescence requires careful and faithful oversight. Fifteen is a large percentage to be due to one complication.

This examination of fatal diphtheria cases has strengthened the belief in my mind that we possess adequate means for the general control of the disease in our diagnostic facilities and in our remedy, antitoxin. We seem to be still weak in our knowledge of the nature and action of this remedy and we show consequent hesitancy in applying it in its most effective form in the critical case. Both medical and lay persons still have wrong impressions regarding its powers and the dangers connected with it. The degree of our success in the clinical control of this disease will depend on the dissemination of accurate knowledge concerning it and concerning the nature and action of our effective remedy for it.

### DIPHThERIA.

By WILLIAM H. PARK, M.D., NEW YORK.

THE invitation which was extended to me to address this meeting was largely given for the purpose of informing you of the results of the

investigations carried on in the New York City Health Department hospitals and laboratories in the use of the Schick test in estimating immunity and of the toxin-antitoxin mixtures in producing it. I appreciate the opportunity of appearing here.

Before taking up these subjects, I want to say a word about danger from sensitization to serum and the dosage of antitoxin. These subjects have already been ably discussed by Dr. Hitecock. So far as the danger of a repeated injection is concerned, I have long learned to have no fear of a second subcutaneous injection in those sensitized by a previous one. We have never had, in New York, a fatal accident from any injection except the first, and if it ever happens in other localities, it must be very exceptional. In fact, it has seemed to me that a person who has had a previous injection without serious results is insured against a fatal accident from any subsequent injection. An accelerated reaction is frequently met with, but this is disagreeable rather than dangerous. Sudden deaths have occurred in those having the condition of status lymphaticus and severe symptoms have occurred in those who have suffered previously from asthma. So far as the dosage is concerned, I entirely agree with Dr. Hitecock as to the importance of giving a sufficiently large primary dose, but he disagrees somewhat from me in the opinion that if an insufficient dose is given later, a larger dose will remove the harm of not having given sufficient at the first dose. Unless the first dose is very small indeed, the second and third doses have practically no effect. The toxin left untouched by the insufficient dose has acted and cannot be neutralized. A subcutaneous injection of antitoxin is supplying antitoxin to the blood for at least 48 hours from the time of the injection. The antitoxic globulin is very slow to be absorbed. We do not give the amount of antitoxin which we do because of any definite amount of toxin in the body which we are trying to match. Ten thousand units of antitoxin will undoubtedly neutralize 1000 times the amount of toxin in any case. We have frequently tested the amount of toxin in the serious cases entering the hospital and we have never found more than a fraction of a fatal dose for a guinea pig in 1 cc. of the serum. The large injection is given to lessen the interval between the injection and the absorption of sufficient antitoxin by the blood and its later passage to the lymph throughout the body and its access to the cells.

Before considering immunization, I wish to state a word about our having returned to the old practice, in New York, of requiring a period of 12 days before examining throat cultures for the removal of quarantine.

Investigation showed us that about 25% of the cases cleared before the twelfth day on two primary cultures were found to be still infected

when repeated and somewhat more careful cultures were made. As the majority of these mistakes were, as stated, before fourteen days, we decided to go back to our early methods and require twelve days after the beginning of illness before examining cultures for clearance. This does not prolong the average period of isolation for more than a day or two and it gives the family a definite period of 14 days to look forward to as the probable limit of isolation.

The use of the toxin-antitoxin mixtures to immunize children is an interesting recent development which has been taken up years after the experimental evidence suggesting it was obtained. Babes was the first to show definitely that if antitoxin was added to toxin just sufficiently to neutralize it so that it would not cause destruction of life in the guinea pig, it still did not prevent the toxin from causing, in the body of the injected animal, the production of antitoxin. Later, the different laboratories producing antitoxin confirmed his results and some used the mixture practically in the immunization of horses. Since 1897, the Health Department horses have been started with the toxin-antitoxin mixture. Several years ago, Dr. Theobald Smith definitely suggested, after experimenting with guinea pigs and showing the long immunity given by the mixture, that children be immunized. It remained, however, for von Behring actually to use it. His use of it was made practicable by the previous discovery of Schick,—that by the use intracutaneously of injections of minute amounts of toxin human beings could be divided into those which had antitoxin immunity and those which had not. The former were immune, while the latter were subject to possible infection. As you all know, he injected intracutaneously  $1/50$  of a fatal dose of toxin contained in  $1/10$  of a cc. of salt solution. We have usually used  $2/10$  of a cc., containing the same amount of toxin. Other modifications have been suggested, as for instance, Koplik uses a minute amount of the undiluted toxin held in the point of a needle. This loaded needle is simply inserted intracutaneously, and withdrawn after a few seconds.

Dr. Zingher, in the Health Department Laboratories has devised a very simple method of preparing the test toxin to be given in the usual way. A sufficient amount is placed in a glass capillary tube. This blown into 10 cc. of salt solution gives a strength in which  $2/10$  of a cc. contains  $1/50$  of a fatal dose. This dilution is not stable, and should be used only on the day upon which it is made. The undiluted toxin is quite stable when kept cool and protected from access of air.

We have now used the Schick reaction in some 12,000 healthy children in institutions, and in some 1500 convalescing cases of scarlet fever. As you know, infants at birth have an immunity transmitted to them from their mothers. This antitoxin is gradually eliminated, so that

in from six months to two years, it has disappeared. At about six months of age a certain proportion of children begin to produce antitoxin, and as they grow older a larger and larger proportion develop immunity. There is, therefore, a larger and larger proportion of susceptible children during the first few months of life, and then a lesser and lesser proportion as the self-developed immunity appears. In healthy children between two and four years of age, we have found 32% positive; from four to five years, about 25%; and for the following years, about 20%. That is, some 70% of all children are immune and some 80% adults. Curiously enough, it is found that among the children convalescing from scarlet fever there are about 50% more susceptible persons than among healthy children of the same age. This discovery probably accounts for Schick's greater percentage of positive reactions. Either those lacking immunity to diphtheria tend also to lack immunity to scarlet fever, or the disease itself lessens the amount of antitoxin.

Without the Schick test, all people exposed or to be possibly exposed to infection would have to receive either a passive or an active immunization if we wished to immunize them. The Schick test enables us to dispense with such immunization in about 70% of all cases. All who have used the Schick test know that it must be used with care. It is absolutely necessary to be sure that the toxin is of about the strength desired, because if it has deteriorated, of course no positive test develops in the susceptible. With suitable toxin, a negative test probably gives us absolute security that the case cannot become infected with diphtheria. There is a possible exception in very young infants, in which some claim a reaction does not develop with the usual strength of toxin, even though immunity is absent. A positive test may or may not be a real test, as a slight amount of diphtheria bacillus substance passes off to the culture fluid with the toxin, and this or the peptone may give a pseudo-reaction in those having antitoxic immunity. This occurs more quickly, and disappears more quickly than the toxin reaction. It is well in important cases to give either some heated toxin or some fully neutralized toxin as a control in order to differentiate between the true and pseudo-reactions. Cases that develop antitoxic immunity naturally probably remain immune for life.

*The Immunizing Injection.* The antitoxin is added to the toxin in sufficient amount so that an amount of the mixture containing an  $L^+$  dose of toxin produces a very slight local inflammation, but does not cause death of the injected guinea pig. We have injected a child under one year with about  $1/2$  of an  $L^+$  dose of neutralized toxin; a child under two, a full  $L^+$  dose; a child under four,  $1 1/2$   $L^+$  doses, and after that age, two full  $L^+$  doses. All injections are made subcutaneously. We have tried

in some cases a single injection, in others two and others three. The exact amount of the neutralized toxin and the number of doses is still under investigation. If people are injected who have natural antitoxin, a very rapid response is made, and within seven days marked antitoxin accumulation is obtained. In those, however, who have no antitoxin no appreciable response takes place for fourteen days, and in 50% not before four weeks. Not until three months does the full response take place. A quicker and more abundant production of antitoxin occurs after three immunizations than after two, but even after one immunization some 95% of the children are immune after three months. We have traced these children for from six months to a year and a half, and up to the present time, practically every case has remained immune. These 1200 children are in institutions and they will be tested every three months. Within a few years we will know definitely the length of the immunity. The very same results are found in animals, those having natural immunity responding rapidly and the others slowly, to the injections.

It is important to remember that only 95% of the susceptible become immune, and the remaining 5% of the non-immunes must be protected by antitoxin, in the presence of infection. We find that so far as the deleterious effects go, about 4% of the children show a marked reaction for twenty-four to thirty-six hours. We have seen no deleterious effect after the reaction has subsided. In about 10%, we have a rise in temperature of two degrees, and there is a local swelling, which seemed to be due more to anaphylaxis than to a toxin dose.

The results so far obtained prove that, while the toxin-antitoxin solution will not give any appreciable immunity until the lapse of at least two weeks, and usually not until four to twelve weeks, it will finally produce a lasting immunity in at least 95% of all children. It has, therefore, already become a practical measure in institutions. Its wider use must be determined after considering the degree of danger and the ease of administration. The Schick test has become established as one of great practical value.

#### VII.

### WHOOPIING COUGH: THE MEASURES TO BE TAKEN FOR ITS CONTROL AND PREVENTION.

By JOHN LOVETT MORSE, M.D., BOSTON.

THE mortality from whooping cough in children under five years of age in thirty states in 1911 was 6251; from scarlet fever, 4232; and from diphtheria, 9579; 3860 children under five years of age died of bronchitis and bronchopneumonia during the same period in eleven states in which 1216 died of whooping cough.

A considerable proportion of these cases were undoubtedly secondary to whooping cough, and should be charged up to it. The morbidity, mortality and percentage death rate of some of the most common infectious diseases in Massachusetts in 1915 were as follows: These figures are, however, owing to the imperfect regulations regarding vital statistics, only approximate.

Disease.	Morbidity.	Mortality.	Percentage Deaths.
Measles .....	22,356	142	0.6
Scarlet fever .....	8,520	189	2.2
Whooping cough .....	7,029	202	3.7
Diphtheria .....	9,330	648	6.8
Typhoid fever .....	2,189	195	8.9

In Boston, in 1915, there were reported 388 cases of typhoid fever, with 40 deaths; 2190 cases of whooping cough, with 111 deaths; 2959 cases of scarlet fever, with only 79 deaths; and 2942 cases of diphtheria, with 218 deaths.

It is evident from these figures that, instead of being a trifling affair, as it is usually considered to be by the laity and also, unfortunately, by many physicians, whooping cough is a most serious and fatal disease. It is certainly important enough to deserve, or rather to demand, far more strenuous efforts for its control and prevention than have been given it in the past.

There are certain other points in relation to the mortality from whooping cough which are also of great importance: 57% of the fatalities in the United States in 1906 were in the first year, 23% in the second, 8% in the third, 4% in the fourth, and 2.5% in the fifth year; that is, about 95% in the first five years of life. These figures are corroborated by many other more recent, but smaller, statistics. It is a comparatively mild affection in healthy children over five years of age, and after puberty it is rarely fatal. The importance of these figures will be evident when the measures to be taken to control the disease are considered.

The first thing to be done in the fight against whooping cough is to convince both the laity and physicians of the seriousness of the disease, and of the necessity for its control and prevention. Nothing of importance can be accomplished until they are so convinced. The only way in which they can be convinced is by a campaign of education, which must be led by the United States Public Health Service, the boards of health of a few of the states and large cities, and the pediatricians, who at present seem to be the only ones who appreciate the importance of the subject. How much such a campaign is needed is evident when it is realized that whooping cough is a notifiable disease in less than three-quarters of the states, that isolation is required in only one quarter of them, and then rarely enforced, that at least two states have no law forbidding the attendance of children ill with whooping cough at school, and that many other states allow the other children in the family to attend school, whether they

have had the disease or not. The regulations of the cities are better than those of the states, but many of them do not require notification, almost none of them isolation, and in several, children ill with whooping cough are allowed to attend school.

Physicians can be educated by lectures, circulars, articles in the medical journals and more stringent regulations for the control of the disease. Nothing will educate them more quickly than the imposition of fines for the failure to report cases of this disease. The laity can be educated by articles in the newspapers and monthly magazines, circulars, instruction by visiting nurses, advice of physicians, and the establishment and enforcement of stringent regulations as to the isolation of children ill with it.

It is necessary, in order to make satisfactory regulations for the control and prevention of a disease, to know in the first place what is the cause of the disease. If its cause is a micro-organism, it is also necessary to know how it enters and leaves the body, its habitat in the body, and its habitat and viability outside of the human body. The fact that the causative organism of a disease is known is of comparatively little avail, unless the early symptoms of the disease are sufficiently characteristic to suggest its presence, and the time at which it is contagious is known.

The recent investigations of Mallory have proved conclusively that the Bordet-Gengou bacillus is the cause of whooping cough. It is probable that there are many strains of this organism. The Bordet-Gengou bacillus enters the body through the mouth and nose. Its habitat is the respiratory tract, chiefly between the cilia of the epithelium lining the trachea and bronchi. It leaves the body in the secretions of the respiratory tract. It is present in the sputum in the catarrhal stage, and is most abundant at this time and in the first two or three weeks of the spasmodic stage. It has been found in the sputum as late as the eighth week of the spasmodic stage. It is fair to assume, therefore, that whooping cough, while most contagious during the catarrhal and early weeks of the spasmodic stage, is also contagious throughout the whole of the spasmodic stage. Kittens, puppies and monkeys may be infected with the disease. This probably happens so seldom under ordinary conditions, however, that infection from animals can, for all practical purposes, be disregarded. The Bordet-Gengou bacillus is very easily destroyed outside of the body. Indirect contagion is, therefore, very unusual, and of but little importance.

The staining of smears of the sputum by proper methods gives reasonably satisfactory results in the early stages of the disease. The organisms become progressively less numerous, however, and cannot be recognized if there is a complicating bronchitis or bronchopneumonia.

There is considerable danger, however, of mistaking the influenza bacillus for this organism in sputum. It is very important that the sputum to be examined is obtained from the trachea and bronchi, and not from the secretions of the nose and throat. The isolation and recognition of the organism by cultures is, however, too complicated a procedure for practical everyday use. It can only be done by an expert, and requires a considerable length of time. This method is, therefore, not practicable at present for preventive work.

An agglutination reaction is present in many cases, but it is not constant, and is usually not very high. Its presence is proof of whooping cough; its absence does not count much against it. A complement-fixation reaction is present in a considerable proportion of children ill with whooping cough and convalescent from it. The general experience has been that this reaction is seldom present earlier than the fourth day of the paroxysmal stage, at a time when anyone can make the diagnosis on the presence of the whoop and characteristic paroxysms. Friedlander, however, claims, by his special method of performing the test, to have obtained positive results in nearly 100% of cases in the catarrhal stage. The reaction is stronger during convalescence, and may persist for a good many months. Both of these tests are, however, too difficult of performance to be of practical utility for everyday use. The complement-fixation reaction should, however, especially if Friedlander's results are proved to be accurate, be of great service in the recognition of abortive and atypical cases under exceptional circumstances, when such recognition is of great importance.

There is an increase in the total number of white corpuscles, with an absolute and relative increase in the number of lymphocytes, in the catarrhal stage of whooping cough. The leucocytosis and lymphocytosis increase with the severity of the disease, reaching their highest point in the paroxysmal stage. There is either no leucocytosis or a leucocytosis with a relative increase in the polymuclear neutrophils, in the diseases with which whooping cough may be confused. This blood formula is a fairly constant one in whooping cough, and would be expected, therefore, to be of considerable assistance in its diagnosis before the appearance of the characteristic whoop. It is, however, not always present and may be absent, if there is some complication which is accompanied by a polymuclear leucocytosis. While, therefore, of some assistance in the early diagnosis of whooping cough, it cannot be trusted implicitly.

It is evident that, while the examination of the blood and sputum and the complement-fixation test are of undoubted value in the diagnosis of whooping cough, they are not at present of great practical utility in the recognition and prevention of the spread of this disease. It is

probable that in the future, with improvements in bacteriological technic, they will be of more assistance.

The greatest obstacles to the control and prevention of whooping cough are the facts that the early symptoms are so indefinite, that it is most contagious at the time when it is impossible to recognize it clinically, and that extremely mild types of the disease are not at all uncommon. It is possible, too, that whooping cough may, like certain other diseases, be spread by healthy "carriers." These facts should not be used, however, as arguments against the isolation of children ill with whooping cough, because whooping cough is undoubtedly contagious after its nature is plainly manifest. There is no reason why a child known to have whooping cough should be allowed at large to spread contagion, simply because it may have infected others before it was known to have the disease. An ounce of prevention may not be as good as a pound, but it is, nevertheless, an ounce.

Whooping cough must everywhere be made a reportable disease, and the same penalties imposed for failure to report it as in the case of smallpox, scarlet fever and diphtheria. The health authorities are then in a position to instruct the parents as to the seriousness of the disease, the way in which it is spread and the measures to be employed to prevent contagion. The importance of preventing babies from having the disease should be especially emphasized. The sputum and vomitus should be treated in the same way as in tuberculosis. The house should be placarded. It may be that this is not of great importance. It does, however, enable people to keep away from places where there is known to be contagion, if they wish to do so. It certainly seems reasonable to give people a chance to avoid known exposure, even if they cannot keep away from unknown contagion. The point to be especially aimed at in the isolation of whooping cough is to prevent the infection of babies and young children. The patients should be separated from the other children in the family, if they are under five years of age. If such separation is impossible, the patients should be removed by the health authorities to special hospitals provided for the purpose. These hospitals should be constructed on the "shack" plan, in order to give the children the maximum amount of fresh air, and thus to prevent the development of complications and cross-infection, and so situated that the children can be up and out of doors in suitable weather. There is no reason why children should be isolated in one room and not allowed to go out of doors, provided they are kept away from other children. They ought not to be allowed on the street at all during the acute and most contagious stage of the disease. Later, it may be allowable for them, provided they are attended by an adult. In order to protect other children

in case they do get on the street, they should be required to wear an arm-band of some prescribed color and labeled "whooping cough," in large letters. Arm-bands have been objected to and even ridiculed by certain writers. They claim that they are useless and unnecessary. It does not seem to me that they are, however, as there is no other way in which others can know that a child has whooping cough, unless they hear it whoop. If the child is labeled, careful parents can keep their children away from it. There is no other way in which children with whooping cough can be promptly recognized and certainly excluded from places of public congregation and public conveyances, which, as everyone agrees, should be done. It would not be a bad plan to compel children who have been exposed to whooping cough also to wear a band. Children who fail to observe the quarantine regulations should be at once sent to the hospital by the public authorities, no matter what their circumstances or social position.

There is considerable difference of opinion as to how long quarantine should be kept up. Some authorities believe that, as the Bordet-Gengou bacilli are seldom present in large numbers in the sputum after the first two weeks of the paroxysmal stage, it is useless to continue the quarantine beyond this period. This does not seem to me to be a reasonable position, because the organisms have been found as late as the eighth week, and because in the later stages of the disease the organisms, although they may be present, are very difficult of recognition on account of the large number of the other bacteria. Still other authorities fix a certain number of weeks as the period of quarantine, without regard to the severity and duration of the symptoms in the individual case. It would seem more reasonable to fix the time of quarantine at one week after the cessation of the characteristic paroxysms, as these paroxysms presumably mark the active period of the disease. If such a regulation is not feasible, a quarantine of five or six weeks is a reasonably safe one. It is to be hoped that in the future such advances will be made in the recognition of the Bordet-Gengou bacillus, both in smears and cultures, that the period of quarantine can be regulated in the same way as is now done in the case of diphtheria.

The vitality of the Bordet-Gengou bacillus outside of the body being slight, formal disinfection is not necessary. Thorough cleaning and airing of the premises is all that is required.

The other children in the family should not be allowed to attend school unless they have already had the disease or until two weeks have elapsed since the last exposure, provided they are free from catarrhal symptoms. It is possible that this period of two weeks may be too short, the evidence as to the length of the incubation period of whooping cough being unsatisfactory. Present observations seem to

show, however, that it varies between two and ten days. Two weeks should, therefore, be amply sufficient. Children with catarrhal symptoms, in whom there is any reason to suspect the possibility of whooping cough, should also be excluded from school.

It will be impossible to control whooping cough properly and prevent its spread until hospitals for the accommodation of children ill with whooping cough are established by the community. Such hospitals are necessary for several reasons: first, to take care of those children whose parents, because of poverty or ignorance, cannot give them proper care and isolation at home; second, to protect the public by isolating those children whose parents are unwilling to obey the regulations as to quarantine; third, to give suitable hospital treatment to babies and children seriously ill with the disease, and its complications—bronchitis and bronchopneumonia.

Objections to the establishment of hospitals for the care of whooping cough have been raised on the grounds that only a small proportion of the cases can be taken care of; that on account of the difficulty in recognizing the disease in its early stages, when it is probably most contagious, the children are admitted too late to afford much protection to the public, and that there is great danger of cross-infection and the development of bronchopneumonia in hospitals. The first two objections are, to a certain extent, valid. It does not seem reasonable, however, to argue that it is needless to do anything to protect the public from whooping cough simply because the protection afforded cannot be made perfect. It seems to me that a little protection is better than none. Experience in hospitals built on the "shack" plan, in which the patients get an abundance of fresh air, has shown that the last objection has no foundation in fact.

It is obviously impossible to treat children ill with whooping cough in dispensaries or outpatient departments where other children are treated. It would be hard to find better places in which to spread contagion. Nevertheless, there are a large number of ambulant cases of whooping cough which would be benefited by treatment in dispensaries. Dispensaries for the treatment of whooping cough, and nothing but whooping cough, should, therefore, be established in the thickly settled portions of our large cities. The patients treated should, however, come only from the immediate neighborhood, because of the danger of spreading contagion if they come in public conveyances. The City of New York established such a clinic not quite two years ago. The results obtained have been most satisfactory, and warrant the establishment of more stations.

It is obvious that, if there was some method of treatment which had a curative action in whooping cough and would protect against the

development of the disease, it would aid more to control, prevent and diminish the mortality from whooping cough than all the other means which have been considered together. Such an action has been claimed for the vaccine treatment. Hartshorn and Modler, writing in August, 1914 (*Archives of Pediatrics*, 1914, xxxi, 586), reviewed all the literature of the subject up to that time, a total of 1445 cases. They concluded that there was no universal endorsement of the vaccine treatment, although there was a striking lack of negative reports, that there was no definite standard of dosage, and that the dosage had apparently often been too small. They decided that its value as a prophylactic agent was undetermined, that the earlier the treatment was begun the better were the results, and that it was worthy of a more extended trial. Their own results in seventeen cases were inconclusive. Their conclusions represent the consensus of opinion of conservative observers at that time. The results of Hess (*International Clinics*, 24, s. iii, 97), Frankel (*Kentucky Medical Journal*, 1915, xiii, 458), and the New York City Board of Health, reported by Luttinger (*New York Medical Journal*, 1915, ci, 1043), are, however, more favorable. Hess used the vaccine as a prophylactic in an epidemic of whooping cough in the New York Hebrew Asylum; 244 children were given the vaccine and only 21 developed whooping cough, a percentage of 8.6; 131 others were not given the vaccine. A considerable proportion of these were babies who had practically no exposure. Sixty of 80 who were exposed, or 75%, developed the disease. Frankel gave prophylactic injections to 10 babies in an institution, who were constantly exposed. None of them contracted the disease. Luttinger gave nine prophylactic injections and none of the children developed pertussis. He also treated 138 children with vaccines, 115 of them being within the first three weeks of the paroxysmal stage. In comparison with a control series treated in other ways, the paroxysmal stage was shortened by over two weeks. There was, moreover, a prompt amelioration of the symptoms in nearly all cases. These results seem to show that vaccines are of considerable value as a prophylactic against whooping cough, and that they have some curative action after the disease is established. It is to be hoped that these results will be confirmed in the future. At present they certainly seem to make it advisable to use vaccines as a prophylactic, and justify their further trial in the treatment of this disease. The most favorable results have apparently been obtained with polyvalent stock vaccines. The dosage recommended by the New York City Board of Health for prophylaxis is, for children, 500 millions, one billion and two billions, at three-day intervals. They advise for treatment, an initial dose of 250 millions for children less than one year old, this dose to be

doubled every second day. Children over a year receive an initial dose of 500 millions. The dose may be increased as high as 10 billions.

If the vaccines prove to have the value in prophylaxis and in treatment which the results of the last two years suggest that they may have, the control of whooping cough will be a relatively simple matter. Even if they do not, however, it can be confidently predicted that when physicians and the public understand what whooping cough really means, when proper regulations for its control are established and enforced, and when sufficient hospital and dispensary accommodations for its care are provided, whooping cough will cease to be the scourge which it now is.

### Book Reviews.

*The American Year-Book of Anesthesia and Analgesia.* Edited by F. H. McMECHAN. New York: Surgery Publishing Company. 1915.

This publication has been established for the collation of the world's scientific research on anesthesia and analgesia and represents the collaboration of well-known experts in the various fields of these subjects. It is the intention that this first issue should summarize the progress in them to the present time. Subsequent issues, by means of collected abstracts, are to continue the revision of these subjects as necessity arises and will deal also with other new subjects of equally interesting importance. This volume contains thirty-one articles on selected topics. Among these may be noted one by Dr. George W. Crile of Cleveland on "Anesthesia, Anemia and Resuscitation;" by Dr. James Taloe Gwathmey of New York City on "Ether-Oil Colonic Anesthesia;" by Dr. Kurt A. Thoma on "Local Anesthesia for Dentistry;" by Dr. Yandel Henderson and Dr. W. T. Porter of New Haven, Conn., and by Dr. George G. Smith of Boston on spinal anesthesia in neurology. The work is illustrated with a large number of excellent figures and constitutes a useful contribution to the knowledge and progress of anesthesia.

*Diseases of the Skin.* By RICHARD L. SUTTON, M.D., Professor of Diseases of the Skin, University of Kansas School of Medicine, 693 Illustrations and 8 Colored Plates. St. Louis: C. V. Mosby Company. 1916.

Dr. Sutton has written an excellent textbook along the lines that he has chosen, his purpose being "to present the entire subject of dermatology in a comprehensive and at the same time concise manner." The style is clear and succinct, and the wording well chosen and plain

a model of its kind, in the midst of the number of loosely written treatises that have appeared of late years. Besides a proper amount of space devoted to the more common dermatoses, the author has added a few valuable and timely words on subjects that are of considerable dermatological interest, but are accorded as a rule either a brief notice or none at all. Among these subjects may be mentioned "X-ray and Radium Dermatitis," "Tattoo Marks and Powder Stains," "Paraffinoma," "Frambesia," and "Brown-tail moth." On the subject of treatment he is refreshingly concise and logical, maintaining a wise conservatism on many of the newer methods that are still *sub judice*, but that have been over-exploited by those ever ready to seize the innovations, while forgetting the services that have been rendered by the well-tried procedures. For example, with regard to the vaccine treatment of acne, he voices the judgment of the majority of experienced dermatologists in declaring that it has proved extremely disappointing, and adds that he has practically abandoned its use. The book is a thoroughly American book, and gives a considerable prominence to the views and to the work of American authors. The illustrations are all excellent, and do not comprise any of the time-honored but antiquated reproductions that mar so many of the textbooks with which we have of late been swamped. A number of inaccuracies and typographical errors will be rectified in the succeeding editions. The author is to be congratulated upon having outstripped most of the recent competitors in this field of medicine.

*An Index of Treatment.* By various writers. Edited by ROBERT HUTCHISON, M.D., F.R.C.P., and JAMES SHERREN, F.R.C.S. Revised to conform with American Usage by WARREN COLEMAN, M.D. Seventh Edition revised and enlarged. New York: William Wood & Company. 1915.

The sixth edition of this standard work on therapeutics was reviewed in the issue of the Journal for October 3, 1912 (Vol. CLXXIV, page 481). In this seventh edition all the articles have been thoroughly revised and in many cases rewritten. Several new articles have been the psychoneuroses. In this American edition the dosages of drugs have been modified to conform with the United States Pharmacopoeia and National Formulary. The text of the English edition has also been slightly altered in a few articles. The subjects, which are arranged alphabetically from abdominal myiasis to yellow fever, have been contributed by a number of distinguished physicians and surgeons. In this edition Mr. Sherren replaces Mr. H. Stanfield Collier as surgical editor. An appendix contains a number of useful prescriptions and the entire work should continue its popular practical value to the profession.

# THE BOSTON Medical and Surgical Journal

Established in 1812

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, NOVEMBER 16, 1916.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

An editor will be in the editorial office daily, except Sunday, from twelve to one-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish one hundred reprints free to the author, upon his written request.

The Journal does not hold itself responsible for any opinions or sentiments advanced by any contributor in any article published in its columns.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager,

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

## ANCIENT HISTORY OF YELLOW FEVER.

SEVERAL interesting documents pertaining to the earlier history of yellow fever in the United States, which have recently come to our attention, illustrate interestingly the rapidity with which medical progress, viewed in retrospect, has advanced in the light of discoveries made not really so long ago, yet proving revolutionary in their consequences. One of these documents is a clipping sent by a Boston physician, a former editor of the JOURNAL, from a newspaper of September 17, 1873, describing an epidemic of yellow fever then in progress at Shreveport, La. A telegram to New York on September 16 stated that there were then six hundred cases of the disease at Shreveport and not enough well people left to care for the sick. "The fever is unusually fatal. It is believed to be Mexican vomito introduced by a circus." Evidently the fever was at the same time prevalent also at

Memphis, Tenn., Little Rock, Ark., and other points throughout the South. A news report from Memphis on September 16, 1873, said:

"There is no abatement of the yellow fever, though its ravages are almost exclusively confined to the northwestern portion of the city, adjacent to the mouth of Wolf River, where it first appeared. It is impossible to obtain reliable data in regard to the mortality, but it is evident that there is no decrease in the death rate. The city authorities today took the first steps towards meeting the exigencies of the occasion. The whole street force is being put to work distributing coal tar and burning it in the infected quarter. The white citizens met and organized a Howard Association. The association will open an office tomorrow, and be prepared to furnish nurses and relief to all who apply. Physicians are advising all that can to leave the city, and the trains in all directions are crowded. The wildest reports are circulated throughout the country in regard to the number of dying, but it is safe to say that since the disease appeared the number of deaths from all causes has not reached twenty on any other day, and since the flight of the horror-stricken ones there is less excitement than during the prevalence of the cholera."

The following sketch of the city of Shreveport at that time presents a vivid picture of the local conditions of suffering, apprehension and disturbance of daily life produced by a typical yellow fever epidemic in the days before knowledge had robbed the disease of its terror.

"Shreveport, where the yellow fever has been creating such terrible havoc, is the second city in Louisiana, both in population and commercial importance, it being the great centre of trade for the Red River country. Before the war it had about three thousand inhabitants, but on the close of the war many Northern men went into business there, and the place became an active, enterprising business city, rapidly growing in population, until it is now estimated to have between 10,000 and 13,000 inhabitants. It owes its commercial importance to the fact that it occupies the only available site on the Red River for such a place, there being no good landing place on the west bank of the river within a hundred miles. The Red River valley is the richest region in the country for the production of sugar and cotton, and this makes Shreveport one of the greatest markets in the valley of the Mississippi, or its tributaries, for those staples. Shreveport is something like five hundred miles up the Red River, and is one hundred miles west of Vicksburg. It is at the head of steamboat navigation, and fifteen miles below the great Red River raft, which is one of the most remarkable formations in the world, being a mass of logs and driftwood over forty miles long, and entirely choking up the great stream, which is over 1200 miles long, or, including the

South Fork, 2100. This raft turns the water of the river over the adjacent country, forming great bayous, through which, at high water, steamboats pass around the raft. It has been forming for many years, and is now being removed by the national government. The work is prosecuted by blasting, and when the improvement is completed, steamers will be able to go without interruption up to Fulton, and at high water the river will be navigable as far as the confluence with the branches. Shreveport is on high ground, forming a bluff at the river bank, and is well situated for drainage. The whole country around is flat, and for miles and miles there is one continuous succession of marshes, swamps and bayous, for over one hundred miles to the west, there being one chain of the great bayous formed by the raft. Though at low water a great surface is exposed to the action of the sun, making the surrounding country subject to malarial influences in the hot season, still the health of the city has generally been good. This is the third time the place has been visited by the yellow fever to any extent since it was settled, the first time having been in 1853, and the second in 1867. There has, however, never been anything like the terrible pestilence which is now devastating the place. Many who are conversant with the matter, charge the affliction directly to the Kellogg government. For several months the place has been without a municipal government, the city government elected by the people having been deposed. Those having control of the city have been utterly neglectful of their duty, and the streets were in an indescribably filthy condition. Under the hot semi-tropical sun the reeking heaps of garbage became the sources whence the seeds of the pestilence sprang into active life. The indifference of the lower classes, ignorant of the danger which threatened, aggravated the evil brought about by the criminal neglect of the authorities. Then a steamboat, with hundreds of cattle on board, sunk opposite the city. The cattle were carried down with the craft, and there was no attempt made to move them. The receding waters left the wreck exposed, and there, day after day were seen, in full view, the putrid carcases, rotting in the hot sun, and vultures revelling in carrion. From this sickening stench, powerful and penetrating, was wafted over the unfortunate city, and hastened the coming of the dread disease. The yellow fever soon made its appearance in its most malignant type. Everyone who could left the city, no one remaining behind but the poor and those compelled by the greatest necessity. The present condition of affairs is truly pitiable, and the stricken place deserves the sympathy and aid of our more fortunate citizens.

The second document, to which reference was above made, is a sketch of yellow fever in Florida by a Boston physician, the manuscript of

which is dated December 6, 1888, just ten years before the work of Walter Reed and his commission. The text of this hitherto unpublished sketch is as follows:

"The usual climatic influences of the season of the year may probably be safely relied upon to hold at bay for some months the yellow fever scourge which has presented itself in epidemic form at various points in the state of Florida during the past summer and autumn. The longer and warmer days, however, will soon return, and with the increasing power of the sun all the necessary elements to start into renewed activity the dormant disease-germs which are allowed to linger through the winter.

After the unsuccessful campaign of the season just ended against the disease, the renewal of the struggle is already anticipated with anxious expectation by the inhabitants of the infected communities and by those of neighboring States lying within the yellow fever zone. Questions of prevention are of the first importance, and destruction of disease germs is the problem of the moment.

Among the objects universally recognized as most dangerous foci of infection are the clothing, bedding and personal effects of families among whom cases of yellow fever have existed. There are reasons to believe that by such household articles, yellow fever was carried from Havana to Key West last year.

There is probably but one opinion among competent and impartial judges as to the desirability, we might better say the imperative necessity, for the thorough disinfection, or, where bulk renders thorough disinfection uncertain or impossible, the complete destruction of such suspected articles. On the other hand, the destruction of these things, without compensation, is impossible, whether from the practical or the humane point of view.

Granted that there should be effective destruction, and that there must be compensation, it is simply a question of whence the compensation should come. State rights and privileges should carry with them state duties; but in Florida there is no central sanitary authority, the smaller communities are very poor, and even a city like Jacksonville is said not to be in a condition to do this work for itself, being hampered by a charter provision which forbids an annual expenditure greater than 1% of its assessed valuation; it has no ready funds, and

the Sanitary Auxiliary Association is reported to have recently loaned the city \$5000. Under such circumstances local authorities can hardly be trusted with the execution of the proposed prophylactic measures.

Drs. Porter and Guiteras, as agents of the United States through the Marine Hospital Bureau, have been already engaged in a house-to-house inspection in the city of Jacksonville and elsewhere and have ordered the destruction by fire of such articles as they deem necessary, for which no compensation is provided. Poor people, however, will not give up their bedding to be burned, without compensation, and it seems almost inevitable that the Federal Government must in this instance, however bad such precedents may be, assume the expense, as well as the responsibility, of making such measures as effective as possible. An appropriation of \$100,000 was made by Congress for stamping out the epidemic, and some of this should be available.

On the other hand, even should the necessary funds be available to insure the effective destruction of existing fomites, there seems to be no present security and no reasonable probability of future security against the repeated introduction from Havana of equally pestilential articles. Even a patrol or blockade by United States cruisers of a coast with the length and peculiar characteristics of the Florida coast would offer a poor guarantee against the light-draught, fast sailing "viveras" or fishing smacks and the tramps which carry on a traffic, legitimate or illegitimate, between Cuba and Florida. In all probability, whatever measures are adopted by our own federal or local governments, as long as there exists at the very doors of our Southern States such a breeder of yellow fever as the port of Havana, they will be liable to epidemic outbreaks of this disease. A recent report, even though not confirmed, of the arrival in a New York tenement house of a family direct from Jacksonville, one member of which developed suspicious symptoms, is an indication of what may be anticipated, and serves to remind us that in the questions to which we have alluded, all parts of the country are concerned."

Appended to the above sketch is a note of comment by another physician, then connected with the United States Army Medical Service in Washington, in which he calls attention to

the fact that there are abundant means for disinfecting clothing and bedding, presumably infected by yellow fever, which do not involve their destruction as burning does.

"No one, I presume, doubts that boiling for 15 minutes would be quite sufficient to destroy the yellow fever germ. Nor do I believe it would survive 24 hours' exposure to the concentrated fumes of sulphurous acid. Simple boiling and washing is, however, in my judgment, amply sufficient protection combined with thorough aeration of enclosed spaces. As to the general principle that the United States must do this work if it is to be done, I think no one who is acquainted with the condition of affairs in Southern towns will have any doubt. It may not be according to the Constitution, 'as amended,' but it is a necessity all the same. I have taken the ground for the last eight or ten years, that we have a right to demand of the Spanish and Cuban governments that Havana shall be put in decent sanitary condition, on the ground that it is a standing menace to us, as it now is, and I do not believe that any effectual protection of the Gulf Coast from yellow fever will be attained until we do this."

These two documents, dating less than thirty years ago, and representing the best and most expert medical opinion of their time, afford further and striking evidence of the rapidity of medical progress. The history of yellow fever in America during even the second half of the nineteenth century has become already ancient history. Thirty years hence, when we know the whole truth about poliomyelitis, we may look back in the same manner upon our present theories about its transmission and prevention.

#### PROGRESS OF POLIOMYELITIS.

DURING the past week there has been a definite decline in the prevalence of poliomyelitis throughout the United States. The weekly report of the United States Public Health Service for October 27, 1916, gives the case incidence of the disease in September as follows: New York (exclusive of New York City), 1064; New Jersey, 957; Pennsylvania, 743; Massachusetts, 623; Connecticut, 274; Illinois, 257; Minnesota, 186; Michigan, 166; Wisconsin, 158; Ohio, 138; and Maryland, 100. In October there were 125 cases in Maryland.

In Massachusetts the total number of cases reported in October was 704, with 59 deaths, the largest number in any month during the present epidemic. During the first eleven days of No-

vember 107 new cases were reported in Massachusetts, making a total of 1823 in this State since January 1, 1916.

At its annual meeting in Cincinnati, Ohio, on October 26, the American Public Health Association adopted the following resolution:

"In view of the fact that infantile paralysis has existed for several months and still exists in the United States and Canada, taking on in some localities an epidemic character; that considerable anxiety is expressed by the public generally, and that they, the public, the physicians, and the health authorities may well expect an authoritative statement upon the subject from this Association in annual convention assembled:

"*Be it resolved*, That the president be forthwith authorized to appoint a small committee of specialists and of those who have had experience of the disease with instructions to meet immediately and to prepare a report of the present actual knowledge of the cause of the disease, the manner and agents by which it is spread, the best methods of treatment, and the best preventive measures.

"And that this committee submit its report before the close of this annual meeting, and that such report be given to the public immediately."

In accordance with this resolution, Dr. John F. Anderson, president of the Association, appointed the following physicians to constitute the committee: Dr. Haven Emerson, health commissioner of New York City; Dr. Wade H. Frost, of the United States Public Health Service; and Dr. A. J. Chesley, director of the division of preventable diseases of the Minnesota State Department of Health.

In its report, after summarizing present knowledge of the disease, this committee concluded as follows regarding its prevention, control, and treatment:

"If the foregoing conception of the disease is correct, it is obvious that effective preventive measures, approaching complete control, are impracticable, because isolation of recognized cases of the disease and restraint upon their immediate associates must fail to prevent the spread of infection by unrecognized cases and carriers. These difficulties would appear to be inherent in the nature of the disease. Nevertheless, we may hope for the development of more thorough knowledge, which will permit of more effective control of the disease than is now practicable. Of first importance is the more general recognition by practitioners of non-paralytic cases through clinical observation and laboratory procedures. Lumbar puncture has been shown to offer valuable aid in diagnosis, and a more general use of this test is to be en-

couraged, since it not only facilitates accurate and early diagnosis, but in many cases affords symptomatic relief as a therapeutic procedure. Without undertaking to predict the future progress of research, we may hope for certain possible developments which may afford far more effective control of the disease, with substantial relief from many inconveniences at present inevitable. Among these possibilities we would include a practical test for the detection of all clinical types and carriers, a simple and reliable test for distinguishing between susceptible and insusceptible persons, and means of conferring artificial immunity against poliomyelitis.

"At present our information demands the employment of the following administrative procedures in attempting to control the disease:

"1. The requirement that all recognized and suspected cases be promptly reported.

"2. Isolation of patients in screened premises. The duration of infectivity being unknown, the period of isolation must necessarily be arbitrary. Six weeks has been recommended by the Conference of State and Territorial Health Officers with the Surgeon-General of the Public Health Service as sufficient, and this period has been generally accepted throughout the United States.

"3. Disinfection of all body discharges.

"4. Restriction of the movements of intimate associates of the patient as far as practicable. This should include, at least, exclusion of the children of the family from schools and other gatherings.

"5. Protection of children, as far as possible, from contact with other children or with the general public during epidemics.

"6. Observation of contacts for two weeks after the last exposure."

This report is published in full in the weekly bulletin of the United States Public Health Service for November 3, 1916.

## THE POSITION OF STATE EPIDEMIOLOGIST.

IN another column of this issue of the JOURNAL, we publish a notice of a competitive examination for qualification to the position of epidemiologist in the service of the Massachusetts State Department of Health, with the stated regulations governing the appointment of this official. The attention of interested physicians is directed to this notice. The position is one of value and importance to the public and offers attractive prospect of opportunity for service to physicians properly qualified to undertake it. It is highly desirable that the best fitted

candidate should be obtained for this position, and it is expected that the competition for it will be active.

### MEDICAL NOTES.

**FUMIGATION OF ENGLISH STEAMERS.**—United States Federal Health officials have issued a recent order directing the fumigation of steamers arriving at Boston from certain English ports. The reason for this order is believed to be the occurrence of cases of bubonic plague in these ports. During the period between July 1 and October 27, three cases of the disease were reported at Bristol, two at Hull and five at Liverpool.

**PREVALENCE OF DISEASE IN THE UNITED STATES.**—The weekly report of the United States Public Health Service for October 27, 1916, states that during the month of August there were 28 and in September 15 cases of cerebrospinal meningitis in New York. During September 33 cases of smallpox and 1002 of typhoid fever were reported in Ohio. During the same month there were 28,516 cases of malaria and 455 of pellagra in Mississippi; 725 cases of typhoid fever in New York, 676 in Mississippi, 607 in Indiana, 388 in Michigan, 373 in Kansas, 313 in New Jersey, 308 in West Virginia, and 253 in South Carolina.

**TUBERCULOSIS SUNDAY.**—It is announced that Sunday, December 3, has been selected for the seventh annual observance of Tuberculosis Sunday throughout the United States. Its purpose is to intensify the education of the public on the subject of tuberculosis and the collection of funds for its relief.

**COMBATING INSECTS AFFECTING THE HEALTH OF MAN.**—Continued advances in the work of combating the activities of insects affecting the health of man are reported by the Chief of the Bureau of Entomology of the U. S. Department of Agriculture in his annual report recently issued. In mosquito investigations in Louisiana, a species of mosquito hitherto considered a non-carrier of malarial infection was proved to be a carrier. Studies have been made of malaria, and measures are being evolved to meet plantation conditions.

The "starvation" plan, aimed to exterminate the spotted fever tick of the Bitter Root Valley, Montana, was followed during the year with encouraging success. The plan consists of the removal of the domestic hosts of the adult tick from the infested areas. The Bureau also conducted a campaign of extermination against ground squirrels and other rodent hosts of the immature ticks. Examination of the rodents killed showed 40% lower infestation by the tick than during the preceding year.

The report directs attention to the demon-

stration of the Bureau specialists, that the breeding of flies in manure can be prevented by treating the substance with calcium cyanamid and acid phosphate, which at the same time increase the fertilizing value of the manure.

The Bureau also conducted investigations into methods of lessening fly infestation in packing establishments operated under the Meat Inspection Service of the Department.

### EUROPEAN WAR NOTES.

**MEDICAL ASPECTS OF THE MESOPOTAMIAN CAMPAIGN.**—In the issue of the *British Medical Journal* for October 21, 1916, is published an analysis of Sir Percy Lake's dispatch describing the operations of the British troops from January 19 to April 30, 1916, in their unsuccessful attempt to relieve the siege of Kut-el-Amara. After description of the natural features of the country involved in this campaign, Sir Percy refers frequently to the difficulties attending not only the transportation of troops, munitions and food, but the removal of wounded from the field.

"As far as possible, all the wounded were brought in during the withdrawal, but their sufferings and hardships were acute under the existing climatic conditions, when vehicles and stretcher-bearers could scarcely move in the deep mud."

According to the statement of the late Sir Victor Horsley, quoted in an editorial in the same issue of the *British Medical Journal*, "the immediate cause of the appalling failures in the medical arrangements was the utterly defective transport." Sir Percy Lake, in his general summary, at the conclusion of his report, says, in commendation of the personal efficiency and heroism of the medical corps:

"The energy and devotion to duty shown by the personnel of the medical services deserve commendation. Overworked and undermanned as they were during the advance in January—for the greater portion of the medical organizations then in the country had been shut up in Kut, and the medical units of the 3d and 7th Divisions had only begun to arrive—they did their utmost with the means at their disposal to alleviate the sufferings of the sick and wounded. With the arrival in February of the first river hospital ship, *Sikkim*, and a steady increase in personnel, their power of dealing with the situation was considerably improved, as the action on March 8 showed.

"No report on the medical services would be complete without reference to the splendid services rendered by Mr. T. A. Chalmers, of Assam, who brought out, and himself drove, his specially designed motor boat, *Arick*. He spent his whole time, frequently under fire, in conveying sick and wounded between collecting stations, field ambulances, and river hospital craft in a

manner which no other boat in our possession could have imitated."

Of the military expedition itself, the commenting editorial of the *British Medical Journal* says:

"It would not be easy to mention any British military operation on so large a scale, since Walcheren, which failed so completely, and at so heavy a cost in casualties, medical and surgical, as the attempt to relieve General Townshend's Anglo-Indian force besieged in Kut."

The Walcheren expedition was an unsuccessful and disastrous British campaign against the French in the Netherlands in 1809.

**AMERICAN AMBULANCE AT SALONIKI.**—Report from Paris states that the American Ambulance Field Service of thirty-one ambulances, two supply cars and twenty-five volunteers, left that city on October 12 for Saloniki. This unit, which for the past eighteen months has rendered distinguished service in Alsace-Lorraine and at Verdun, remains in charge of Mr. Lovering Hill of New York, who has been its leader on the western front.

**WAR RELIEF FUNDS.**—On Nov. 11, the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund .....	\$164,208.08
French Wounded Fund .....	132,570.12
Armenian Fund .....	114,856.50
French Orphanage Fund .....	69,594.39
Surgical Dressings Fund .....	56,858.06
Belgian Tobacco Fund .....	43,528.19
Italian Fund .....	27,193.54
Facial Hospital Fund .....	24,491.03
LaFayette Fund .....	20,799.53
P. S. D. Fund .....	10,197.18
French Phthisis Fund .....	6,309.50

#### BOSTON AND NEW ENGLAND.

**WEEK'S DEATH RATE IN BOSTON.**—During the week ending Saturday noon, November 11, 1916, the number of deaths reported was 255, against 182 for the same period last year, with a rate of 17.49 against 12.68 last year. There were 34 deaths under one year of age, against 32 last year, and 66 deaths over 60 years of age, against 55 last year.

The number of cases of principal reportable diseases were: diphtheria, 32; scarlet fever, 18; measles, 10; whooping cough, 6; typhoid fever, 5; tuberculosis, 34.

Included in the above were the following cases of non-residents: diphtheria, 7; scarlet fever, 4; typhoid fever, 1; tuberculosis, 3.

Total deaths from these diseases were: diphtheria, 4; measles, 1; whooping cough, 1; tuberculosis, 14.

Included in the above were the following deaths of non-residents: diphtheria, 1; tuberculosis, 1.

## Correspondence.

### GAPS IN MEDICAL EDUCATION.

Boston, October 27, 1916.

Mr. Editor:

Many years ago I read with pleasure and admiration a book of careful anatomical research written by Dr. John Calvert Donaldson, now of Philadelphia, on the development of the brain, and I remember a sentence which expressed a provisional conclusion with reference to the question whether or in what sense we have a right to expect a gain among the races of men, in respect to the higher mental qualities, as time goes on. The sentence to which I refer was couched in something like the following words:

Knowledge increases, for the obstacles to knowledge are mainly from without; but wisdom lingers, as the rare product of a balanced brain.

The truth of this sentiment has been brought home to me from time to time, as I suppose it is to everyone, through coming indirectly in contact with practitioners who have gained scientific knowledge and scientific skill, which they utilize for the benefit—or otherwise—of their patients, without exerting at the same time a proportionate amount of wisdom in so doing.

It is my belief that medical schools have a certain responsibility in this matter, and that they ought to do their best not to turn loose upon the community men who are skilful and efficient without being wise. In other words, I think that medical ethics, obligations and responsibilities, in a broad sense, need to be preached and studied in greater detail. It has happened to me not infrequently to have had to deal with patients in whose lives, loneliness and sorrow, and temperaments in which fears were based on misunderstandings of themselves, had played havoc both with their happiness and their metabolism, yet who had passed through the hands of one or another scientific colleague whose treatment of them, perhaps based on a single physical examination, had indicated a complete color-blindness to the true merits of the case.

It might be too much to expect that every practitioner should have an adequate knowledge of the science that deals with the mental aspects of a person's life and history, but there is good reason to feel indignant when this ignorance is too gross, and especially when those whom it characterizes strive to fill up the gap in their knowledge by scraping together a few arguments to show the uselessness of the facts about which they are so strangely unaware. A recent experience illustrating certain of these points is, in broad outlines, as follows:

A lady of fine, but over-trusting and profoundly neurotic disposition, is on her way home from a distant sanitarium where she had fallen ill with an acute trouble that had been recognized and treated and from which she was convalescent. Having occasion to stop for a brief time at a city within a day's journey of Boston, and feeling still indisposed, she calls in a local practitioner for adviser. In a physical sense there was not much the matter, and not much to be done. That this was the practitioner's opinion likewise is shown by the advice that the patient received from him. He was evidently a kindly person and his counsel was adequate to the necessities of the case. So far so good, though had his diagnosis been more far-reaching he might readily have recognized that without further ado she might return to her native city (which may, indeed, be "provincial," as is sometimes said, but still can boast of a good practitioner or two, and opportunities for making clinical studies of all sorts when these are called for). But no; kindly though he was, he had also a laboratory and was equipped to be a scientific doctor in the most modern sense. The consciousness of this carried its obliga-

tions. He must *prove* himself a modern scientist, a soldier of this lord. And so the drum had to be beaten, the bugle sounded, the skilled assistants summoned to make more than one analysis of the (practically normal) urine, and then to draw an ounce of blood (drawn on both arms), to be used for chemical investigations of the most elaborate sort. Finally the expired air must also be chemically tested by a method which, as we all know, is of the most delicate description, and which was scheduled for repetition in two days.

It is distinctly to be understood that while these tests were going on the patient was not under close observation, and especially that her diet was under no control whatsoever, so that it is not too much to say that from a really scientific standpoint the results of these careful tests could claim no right to scientific standing. The whole procedure was, in short, a hollow mockery, almost equivalent to the playing of a child with a scientific toy of which he had learned the manipulation. On the other hand, by the time the tests were completed the patient was ready to accept anything that was told her, forgetting or not realizing that her life-long history of emotional strain and conflict had not only received no adequate consideration, but had not been recognized as a factor in *her case*, without a deep knowledge of which these weighable and measurable discoveries could be of little note.

Another instance which in a way was much more aggravated than this, has recently come to my attention, where a lady, known to be on her way to an eminently reputable hospital where she was to be under the care of a man of the best possible standing from every point of view, was positively waylaid by a practitioner whom she called in, in a city where she chanced to stop, with the result that she found herself, after a few days, with a bill on her hands for several hundred dollars, a part of which amount was to go, and did go, utterly in vain, into the pocket of a well-known consultant called from another city, while the rest, equally in vain, went into the pocket-book of the practitioner into whose talons she was so unlukey as to fall.

Such experiences as these justly make one feel indignant. They ought to be exposed and thought about, and those who make it their life study to learn what it really means to have a psychoneurotic illness have a right to feel not only dismay but disgust at the practice of colleagues who use knives and pills and instruments of precision, with great freedom, not alone in cases where these are really indicated as of fundamental value, but in others where their employment is due to the fact that they are tools which their owners have learned to use with a skill the possession of which makes them its willing slave.

JAMES J. PUTNAM, M.D.

## THE TREATMENT OF HIP FRACTURES.

Mr. Editor:—

The JOURNAL of September 28, containing the symposium on fractures, has but just come to my notice; and the incentive for this belated intrusion on the discussion of fracture of the neck of the femur is furnished by the following quotations from Dr. Cotton's paper:

"The best way to be sure of a satisfactory result in hip fractures is to have a system and conviction that makes it unnecessary to look up results."

"Now everyone has been claiming everything for his pet method in all hip fractures."

Being fairly familiar with the literature of this subject, I have attempted to identify the pet methods which have set up the wave of enthusiasm that, according to Dr. Cotton, now ruffles a hitherto stagnant pool.

It hardly seems possible that at this late day any one has become enthusiastic over conventional treatment, for even the Maxwell modification has been before the profession for upwards of 50 years. Nor does the characterization seem to apply to Moore's treatment, because that is a modification of the abduction method in adaptation to infirmity. Nor to the non-treatment of Binnie, although Dr. Cotton "understands it has given good results." Nor to artificial impaction, Steineman's nails, ice tongs, or primary bony pegging, because all these are of admittedly limited application.

I am forced to the conclusion that the abduction treatment best represents what Dr. Cotton has in mind, because it is based on conviction, and because very definite claims are made in its behalf.

To specify: It is claimed that fracture of the neck of the femur of whatever type should be treated like any other fracture, by immediate reduction of deformity, by secure fixation of the fragments, and that these essentials of success should be supplemented by the adequate after-care upon which functional recovery is so largely dependent; that such treatment in a comprehensive sense has been made practicable by the abduction method, because it is mechanically adequate for the purpose, as may be demonstrated by x-ray examination at the time of the operation or thereafter that conventional treatment is mechanically inadequate for the application of surgical principles, because its basis is traction which, at best, is unreliable, and, in this instance, usually futile. The chief dependence for security in the treatment of any fracture is the resistance of the apposed fragments. In fracture of the neck of the femur the fragments are in lateral relation and can be brought end to end only in full abduction, when the leverage of the limb is opposed to the resistance of the tense capsule forces; contact and assures security. This is a mechanical proposition that should be self-evident. It is because of the admitted inadequacy of conventional method in the treatment of complete fracture that deformity, seeming to assure contact, is not corrected in spite of the functional disability that it entails.

Dr. Cotton is obsessed by impaction. In his book he states that 90% of hip fractures are impacted. He reviews conventional methods and, with no mention of after-treatment other than that weight should not be borne earlier than eight or ten weeks after the fracture, concludes that the results are good. He has stated elsewhere that: "It is a crime to disturb an impaction in reasonably good position." Furthermore, the fractures at the base of the neck "get well anyhow, with good or bad treatment, while complete intracapsula fractures never unite under routine treatment." I think it is generally conceded that fracture at the base is the common type. Stimson, for example, examined the x-ray pictures of 64 consecutive cases admitted to the New York and Bellevue Hospitals and found fracture at the base in 48, or 75%.

In spite of this potentiality for repair, Cotton now admits, in contrast to his former optimism, that the results are wretched. As I understand his writings he thinks these results are primarily determined by chance,—the chance of fracture at the base or near the head, the chance of impaction or non-impaction,—and that operative impaction alone holds out a hope for a class of otherwise hopeless cases.

The steps in this operation are to reduce displacement under anesthesia; to mallet the adjusted fragments; to fix the limb in a moderate degree of abduction by a plaster spica, and, judging from the illustrative case treated in the Brigham Hospital, to protect the weak part from weight bearing for many months.

This treatment seems to me decidedly mixed. I Dr. Cotton wishes to test the actual resistance of artificial impaction he should treat the patient as, according to his book, he would treat spontaneous impaction and permit weight bearing in eight or ten weeks. Malleting an already injured bone can serve no other

purpose than to fix the fragments. And how can one assure more pressure than by the leverage of an extended and abducted limb against a tense capsule?

It seems to me that artificial impaction is simply a modification of the abduction treatment, and that when Dr. Cotton has mastered the mechanics of the abduction method as a means of correcting deformity and assuring security, which his own writings prove that he does not understand, he will extend rational treatment to those cases that uniting "anyhow" furnish a large proportion of the wretched results that he deplors.

In my opinion, wretched results in favorable cases are best explained by wretched treatment, wretched in conception and wretched in every detail from beginning to end.

The claims of the abduction treatment are based upon its demonstrated efficiency in applying surgical principles. It has never been claimed that all patients are amenable to efficient treatment, or that efficient treatment will always assure success. It is claimed that by efficient treatment one may provide the opportunity for repair without which failure is inevitable; consequently, that the result is determined primarily by the character of the treatment and by the skill and experience of the one who applies it.

The point at issue is not of the possible advantage of pet methods in adaptation to special cases, but of the establishment of surgical principles of which all treatment should conform and of which, at the present time, the abduction treatment is the only exponent.

Dr. Moore's modification of the abduction treatment seems to have succeeded admirably in the class of cases for which it was designed. It has, however, certain practical disadvantages in that it is more difficult to apply accurately and that the attitude designed to permit a sitting posture is less suitable for recumbency. I should suppose, also, that fixing the limb in flexion at the hip and knee would induce contractions that might be resistant to correction.

Dr. Lovett's suggestion that traction should be added to abduction to assure security, based on his experience in the correction of coxa vara, seems hardly pertinent. When a normal bone is broken, one aims to restore the normal contour by apposing the fractured surfaces and thus to assure security. In correction of deformity one must necessarily place the fragments in a new relation which precludes accurate apposition to one another. If the abduction method is properly applied the fragments are locked, the addition of traction is not only unnecessary, but could be a great disadvantage in preventing the frequent changes of position that the independent splint permits.

The abduction treatment has been so often misrepresented by its upholders and critics that I take the liberty of referring those who may care to inform themselves on the subject to the *Annals of Surgery* of October, 1914.

ROYAL WHITMAN, M.D.

13 Lexington Ave., New York City, Nov. 1, 1916.

## NOTICE OF A COMPETITIVE EXAMINATION FOR QUALIFICATION TO THE POSITION OF EPIDEMIOLOGIST IN THE MASSACHUSETTS STATE DEPARTMENT OF HEALTH.

Although the law leaves the appointment of the Epidemiologist in the hands of the Commissioner of Health, it is the policy of the State Department of Health to hold competitive examinations for such positions and to consider the results of such examinations as the principal basis for selecting appointees.

In Dec. 4, 1916, an examination will be held for qualification to the appointment of Epidemiologist of the Massachusetts State Department of Health.

The written examination will be held on the above date in the examination room of the Civil Service

Commission, State House, Boston. The oral and practical examinations will be held on dates and at places announced at time of written examination.

Persons possessing the necessary qualifications desiring to enter the competitive examination for this position are requested to communicate with the State Commissioner of Health, State House, Boston, at once. Upon such written application, a list of rules and regulations governing the appointment, and an application blank will be forwarded.

Admission to the examination is governed by the regulations accompanying this notice. Physical fitness is a necessary prerequisite, but no percentage credits are given on physique. The examination comprises written, oral and feasible practical tests.

A relative rating will be established on the basis of:

- Previous experience in epidemiological work—maximum, 20 points.
- Results of oral examination—maximum, 20 points.
- Results of written examination—maximum, 60 points.

A. J. McLAUGHLIN, M.D.,

November 3, 1916.

Commissioner of Health.

### STATE DEPARTMENT OF HEALTH OF MASSACHUSETTS. REGULATIONS GOVERNING THE APPOINTMENT OF AN EPIDEMIOLOGIST.

#### 1. Number of appointments.

There will be one appointment made to the position of Epidemiologist.

#### 2. Form of application for appointment.

Candidates for the position of Epidemiologist must make application addressed to the Commissioner of Health, in their own handwriting, asking permission to appear before a Board of Examiners. Candidates shall state their age, date and place of birth, present legal residence, names of colleges or institutions of learning of which they are graduates, date of graduation, and shall furnish testimonials as to their experience and moral character.

#### 3. Time limit for applications.

All applications must be on file in the office of the State Department of Health at least ten days before the date scheduled for the examination.

#### 4. Age limit.

No candidates shall be eligible to appear before the Board of Examiners whose age is less than 23 or more than 35.

#### 5. Professional requirements.

Candidates shall be graduates of an incorporated medical school.

#### 6. Citizenship.

All candidates must be citizens of the United States, and preference in appointment will be given to residents of Massachusetts.

#### 7. Physical examination.

Candidates for appointment must pass a satisfactory physical examination before a Board of Examiners.

#### 8. Scope of examination.

All examinations of candidates for the appointment of Epidemiologist shall be conducted by a Board of Examiners. These examinations shall include physical, oral, written and practical tests in the subjects outlined in the succeeding sections.

#### 9. Board of examiners.

The Board of Examiners shall consist of three or more members. These members shall be selected by the Commissioner of Health, from the Public Health Council or other officials of the Department.

#### 10. Subjects for written examinations.

All candidates for appointment must pass a satisfactory written examination in epidemiology, communicable diseases, preventive medicine and vital statistics.

11. *Compensation.*

The compensation of the Epidemiologist shall be \$2,000 per year at the beginning.

12. *Tenure of office.*

The Epidemiologist may be removed from office by the Commissioner of Health because of gross misconduct or inefficiency, but only after the accused officer has been furnished with a copy of the charges made against him and given a hearing thereon by the Public Health Council.

### CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE TWO WEEKS ENDING OCTOBER 28, 1916.

October 14.

P. A. Surgeon W. H. Connor, detached *Kansas* to *Olympia*.

October 16.

Asst. Surgeon R. M. Waterhouse, to *Melville*.

Asst. Surgeon E. K. Lee, M.R.C., commissioned from Sept. 18, 1916.

October 18.

Medical Director T. A. Berryhill, from Great Lakes Hospital to Mare Island Hospital.

Medical Director M. F. Gates, from Mare Island Hospital to Newport Hospital.

Medical Director L. W. Curtis, from Newport Hospital to Great Lakes Hospital.

P. A. Surgeon I. B. Ledbetter, from Naval Hospital, Las Animas, to Training Station, Great Lakes, Ill.

P. A. Surgeon A. H. Allen, from *Texas* to *Louisiana*.

P. A. Surgeon L. M. Schmidt, from *Louisiana* to Norfolk Hospital.

P. A. Surgeon L. C. Whiteside, to Las Animas Hospital.

Asst. Surgeon R. A. Torrance, to *Texas*.

Asst. Surgeon F. H. Bowman, to *Colorado*.

NOTE: Surgeon J. H. Holloway, retired, died at Albuquerque, N. M., August 2, 1916.

October 24.

Surgeon W. H. Rennie, resignation accepted, effective Nov. 1, 1916.

P. A. Surgeon T. W. Reed, detached Naval Hospital, Norfolk, Va., to Asiatic Station, via November transport.

October 25.

P. A. Surgeon H. L. Kelley, to command Naval Hospital, Port Royal, S. C.

October 28.

P. A. Surgeon S. D. Hart, from Newport Training Station to *Maumee*.

A. A. Surgeon H. A. Giltner, appointed from October 21, 1916, to Navy Recruiting Station, Parkersburg, W. Va.

### SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A meeting of the Society will be held in Sprague Hall, Boston Medical Library, on Monday, November 20, 1916, at 8.15 P.M.

#### PROGRAM

Memorial Addresses, "Dr. William P. Rolles,"

Dr. Charles F. Withington

Dr. Edward Waldo Emerson

Paper on "Sanatoria," Dr. Edward L. Parks

9.00 P.M., Business Meeting.

Question: The Future of the Society.

Every member is urged to be present.

GILBERT SMITH, Secretary.

59 Commonwealth Avenue.

SUFFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Surgical Section will be held at the

Boston Medical Library on Nov. 22, at 8 P.M.

1. Dr. F. B. Mallory, Boston, "The Pathology of Acute Pancreatitis." (With lantern slides.)

II. Dr. John B. Deaver, Philadelphia, "The Surgical Aspects of Pancreatitis." (With lantern slides.)

The discussion of these papers will be introduced by Dr. Joseph H. Pratt and Dr. Franklin G. Balch, Boston.

W. J. MIXTER, M.D.,

Secretary.

CHARLES L. SCUDDER, M.D.,

Chairman.

### APPOINTMENTS.

MASSACHUSETTS STATE DEPARTMENT OF HEALTH.—Dr. Walter H. Brown, epidemiologist of the Massachusetts State Board of Health, resigned his position on November 1, to accept an appointment as executive officer of the board of health of Bridgeport, Conn.

NORTHWESTERN UNIVERSITY.—Dr. Frederic A. Besley has been appointed professor of surgery and Dr. Roy G. Hoskins, associate professor of physiology in the Northwestern University Medical School.

UNIVERSITY AND BELLEVUE HOSPITAL.—Dr. P. Y. Previc has been appointed instructor in physiology, and Dr. E. R. Hoskins and Dr. J. L. Connel, instructors in anatomy at the University and Bellevue Hospital Medical College.

UNIVERSITY OF ILLINOIS.—Dr. L. V. Heilbrun has been appointed instructor in microscopic anatomy at the College of Medicine at the University of Illinois.

UNIVERSITY OF NEBRASKA.—Dr. H. E. Eggers has been appointed professor of pathology and bacteriology, Dr. Amos W. Peters, assistant professor of biochemistry, and Dr. John T. Myers, instructor in bacteriology, in the College of Medicine of the University of Nebraska, Omaha.

MCGILL UNIVERSITY.—Dr. Ardrey W. Downs, formerly professor of physiology at the Medico-Chirurgical College, Philadelphia, has been appointed professor of physiology at McGill University, Montreal.

UNITED STATES HOSPITAL, Manila.—Dr. Fernando Calderos has been appointed director of the United States Government Hospital at Manila in succession to Dr. William E. Musgrave, professor of surgery, and dean of the Medical College of the University of the Philippines.

HARVARD UNIVERSITY.—Dr. Charles L. Scudder, formerly lecturer on surgery, has been appointed assistant professor of surgery in the Harvard Medical School.

### RECENT DEATHS.

DR. LEONARD M. BRADLEY of Milton, Mass., who died at Mattapan, Mass., recently, was born in Milton on March 6, 1879, and had practiced his profession as a dentist in Mattapan for a number of years. He is survived by his widow and one son.

DR. LEWIS DARLING, who died recently at Lawrenceville at Tioga County, Pennsylvania, was born there on Oct. 19, 1840, the son of a physician. He received the degree of M.D. in 1866, from the University of Michigan, after having served throughout the Civil War. He immediately settled in his native town, where he continued in the practice of surgery until his death. He is survived by his widow, three sons and three grandsons.

DR. FRANK D. MAINE, who died on October 29, at Springfield, Mass., was born in 1839. He served throughout the Civil War as a volunteer in the Fourteenth Connecticut Infantry, and after teaching for a time, obtained the degree of M.D., in 1872, from the New York Homeopathic Medical College. After practicing his profession successively in Middletown and Windsor Locks, Connecticut, he removed, in 1892, to Springfield, where he continued active in the profession until his death. He is survived by his widow.

## Address.

### THE PHYSICALLY DEFECTIVE.\*

BY EDWARD O. OTIS, M.D., BOSTON.

WHETHER any of us are mentally perfect is a question, for as Tuke, the great English authority on mental diseases, remarks, it is to be assumed that the deity is sane, but whether anybody else is is a debatable question. At all events, most of us have some kind of a mental bias. Morally, we confess that we are all "miserable sinners"; physically, we are no less imperfect. "There is always somewhere a weakest spot." However, that "weakest spot" does not, with the majority of men, incapacitate them for a man's career in the world. It is only some marked and glaring physical deviation from what we call the normal that places one in the category of the physically defective, and this class is what we have to consider.

Mind and will always triumph over matter, and when the will power is intelligently directed and grimly determined, it will make a defective body do its bidding. Illustrations of this are innumerable, and all of us can doubtless recall examples in our own experience of success attained in spite of physical handicaps. Henry Fawcett became blind through an accident at the beginning of his career, yet later he became professor of political economy at Cambridge University, a writer upon the subject, a member of Parlia-

ment and postmaster-general of England. Huber, the blind naturalist, contributed to entomological science some new observations upon the habits of the bees. It was Milton's blindness which gave us that matchless poem, so sad and yet so triumphant:—

"When I consider how my light is spent  
Ere half my days in this dark world and wide,  
And that one talent which is death to hide  
Lodged with me useless. . . ."

The remarkable development of Helen Keller is familiar to us all. One of our own United States Senators is blind, and an eminent member of our own profession, who has added much to medical literature, has suffered from the same misfortune since youth. Even our friend Silas Wegg, with the handicap of his wooden leg, made the most of his opportunity and won temporary distinction as an educator of the credulous Mr. Boffin.

The men and women, however, who have achieved marked distinction in spite of acquired or congenital physical defects are the exception. Besides the will to succeed and an exceptional mind, they usually enjoyed exceptional opportunities for education. Not so with the great mass of the physically defective. Like the rest of us, they are of mediocre mental inheritance, and a large majority are without means of education, or opportunity of development, unless some assistance is rendered them. Such are the blind, the deaf and dumb, the crippled and deformed, and those suffering from various other physical handicaps. It is, indeed, bewildering, as well as depressing, to consider the vast numbers of this

\* Presented at the meeting of the American Academy of Medicine, at Detroit, June 10, 1916.

kind which the present war is producing at wholesale.

Granted that the physically defective are of sound mind, there is much to be hoped for in their care and education, as experience has shown; the "lame man may not leap as an hart, or the eyes of the blind be opened, or the ears of the deaf be unstopped, or the tongue of the dumb sing," but many, perhaps the most, can be expected to become self-supporting or more; they can be trained to employ the faculties that remain to the best advantage, and thus discount their handicaps.

The legitimate duty of the state is to provide for the welfare of its people,—all its people; and each state must decide in what way and how far it will and can do this. Two fundamental objects, however, are obviously the duty of every well-ordered state: first, to protect its citizens from palpable injurious influences, such, for example, as contagious diseases, impure food and drink, unwholesome conditions in factory and workshop, exploitation of child labor, etc.; hence the free distribution of diphtheria antitoxin, compulsory vaccination, milk and food inspection, the notification of contagious diseases, hospitals for consumptives, etc. Second, to afford its citizens an opportunity for development, a chance to realize that freedom, equality, and pursuit of happiness which are declared to be the birthright of us all in this country; hence the public schools and libraries, and other public educative measures. Furthermore, the public has, to a greater or less degree, taken upon itself the duty of caring for many of its unfortunates in mind or body, both for their own good and also to prevent them from being a source of injury to others, or from becoming dependents; hence the public hospitals and insane asylums, institutions for the feeble-minded, consumptive sanatoria, reformatories for the criminal class, schools or institutions for the crippled and deformed, the blind, and the deaf and dumb.

It is of the three latter classes of physical infirmities that I wish especially to speak, namely: (a) the crippled and deformed, (b) the blind, (c) and the deaf and dumb, for they constitute the major part of those whom we include under the physically defective and for whom legislation has done much, particularly for the blind and the deaf and dumb. For the crippled and deformed the states do not appear to have made equal or adequate provision, although this class probably largely outnumbers the other two classes. "It may be stated in general," says the Secretary of the State Board of Charities of Massachusetts, "that public care of crippled and deformed children, who are not necessarily public dependents, is the rare exception rather than the rule in social development." We still see, all too frequently, the maimed or crippled man selling lead pencils or shoe strings on the street corner, who, with an industrial education, might be setting type or cane-seating chairs and earn-

ing a steady and not a half-begging, precarious income. How much more inspiring is it to undertake the education of a crippled child with a sound mind than to expend the same amount upon a feeble-minded one, who can never be anything but a burden upon the community! How many crippled children and adults there are in the United States no one knows, for, unfortunately, no census of them has ever been taken. Dr. Orr of the Nebraska Orthopedic Hospital estimates the number as 259,000. Prof. Lange, quoted by Miss Reeves,\* stated in 1910 that the number of crippled children under fifteen years of age in Germany was 98,263. One hardly dares to imagine what the number of crippled and maimed adults now is in that unhappy country, which is so rapidly producing them. "If the number of crippled children in this country," says Miss Reeves, "bore the same proportion to the general population as in Germany, there would be about 133,000 crippled children under fourteen years of age, and at present only 4901 are cared for in the 37 existing institutions for them, public and private."

It is evident, then, that a not inconsiderable number of such children, indeed the greater number, are growing up illiterate and without training, owing to their inability to attend the common schools. It would appear to be a duty, as well as an economic measure, for the state to afford these defectives a common school and industrial education, and thus render them self-supporting members of society instead of a burden upon it. There are only five institutions for crippled and deformed children maintained entirely by state appropriations: one each in Massachusetts, New York and Nebraska, and two in Minnesota. Some of the other similar institutions receive public aid, but are controlled and administered by private boards. The "Massachusetts Hospital School" is the largest and most elaborate of its kind in America, and has a capacity for 250 children from five to fifteen years of age who are "mentally competent to attend the public schools." It was established in 1907 by a state appropriation of \$300,000, and the annual maintenance expense at the present time is \$80,000. Besides indicated surgical treatment, the children are given a common school and industrial training. As stated in the act establishing the school, "the purpose (of which) shall be the education and care of the crippled and deformed children of the Commonwealth." Industrial training is given in household arts, sewing, and handicrafts, such as basketry, printing, tailoring, cobbling, carpentry, etc. "The results achieved," says Miss Reeves, "through vocational training evolved from the daily life of a large institution, are most strikingly seen here and at the Widener Memorial School." This latter, the Widener School, is a residential institution, and is probably the most

\* "Care and Education of Crippled Children in the United States," by Edith Reeves, Russell Sage Foundation, N. Y., Survey Associates, etc., 1914.

perfect of its kind in the world, both in the perfection of its plant and in its large endowment of four million dollars.

The New York Hospital for Ruptured and Crippled is a similar institution of the highest development and efficiency, at which graded school work and vocational training are afforded for the deformed children, the City Board of Education paying a certain sum per year for each pupil.

Besides those mentioned above, there are some thirty other institutions of a more or less analogous character, principally established and supported by private charity. Some are called hospitals, some asylum homes, some convalescent hospitals or homes, and others schools; in most of them there is more or less educational work and vocational training.

The greatest need, Miss Reeves found in her investigation, was for children in rural communities, and the only institutions that were adequately meeting this need were the state institutions of Massachusetts, New York, Minnesota and Nebraska.

Besides the residential institutions for the crippled and deformed children, there are day schools, either private or public. In some of the larger cities, as in Chicago, New York, Cleveland and Detroit, special departments or classes are provided in the public schools for such children. The Boston Industrial School for Crippled and Deformed Children is a notable example of a highly-developed day school for such defectives. In this institution, which consists of one large building for general use, and I refer to it especially as it is in my own city and I am familiar with its work, there is a primary and grammar school department, similar to those of the public schools; and manual training adapted to those grades, including paper-folding, clay modeling, basket-making, sloyd, cane-seating, cobbling, needle-work, cooking, typesetting, and printing. Most of the pupils are conveyed to the school and returned to their homes daily, and all receive a substantial dinner at noon. There are also trade classes for those over fifteen years of age, and as soon as they become proficient these workers receive pay. Connected with this school is a modern outdoor schoolroom for those suffering from deformities of a tuberculous origin. Adjustable desks and special seats are provided, cots for rest periods and special gymnastic training are given. A nurse is constantly in attendance, who also visits the children at their homes. There is also medical, surgical and dental supervision and care.

It is evident that state legislation needs to do far more for this hopeful class of young defectives than yet has been done, for, as has been noted above, only about 5000 are at present cared for. Apparently the crippled and deformed do not seem to make quite the appeal to one's sympathies as do the blind or the deaf and dumb.

For the class of indigent adults who are phys-

ically defective from such diseases as arthritis, paralysis, cardiac disease, syphilis and other incapacitating conditions, the state almshouses or workhouses are the common public provision, and all states provide such accommodations, some better, some worse. Private charity also supplements the state provisions by various homes and hospitals, such, for example, as the great Robert B. Brigham Hospital for Incurables, in Boston, with a liberal endowment.

The loss of one of the senses, like that of sight or hearing, seems such an incomparably greater misfortune than to be crippled or deformed, that one's sympathy and pity are more strongly aroused towards this unfortunate class. To be forever shut out from the sight of all the objects of beauty and interest in the world, or never to hear the sound of a friend's voice or the Largo of a Handel is indeed an appealing misfortune, and hence it is that the public early expressed its sympathy in a practical form and began to make provision for the education and training of the blind and the deaf of school age, so that at the present time every state either has its own institutions for the education of those bereft of one or the other of these two senses, or else, as in the case of the smaller or sparsely populated states, makes arrangements for their education at public expense in neighboring states.

As the census report of 1910 upon "Benevolent Institutions" says: "There is probably no one class of persons for whose education and training such complete provision is made as for the blind and deaf." At the twelfth census, an investigation conducted by Dr. Alexander Graham Bell showed that there was a minimum of 64,763 blind persons in the United States, and of these somewhat over half were totally blind and 8000 were under twenty years of age. According to the report of the Commissioner of Education for 1908 there were forty state schools for the education of the blind, with 4340 pupils, and the census of 1910 shows 4720 in such institutions. The education of these children is not regarded as a charity, but as a part of the educational system, carried on at public expense. In 1879 Congress appropriated \$250,000 as a perpetual fund for the purchase of books and apparatus for the different state schools. Normal schools for the blind are also maintained in some states. The first school for the blind established in this country was a private enterprise, that of the Perkins Institute in Boston, founded in 1829 and rendered famous by its two great directors, Dr. Samuel Howe and Dr. Anagnos, and by the remarkable work of the former in the education of Laura Bridgman, who was deaf, dumb and blind. With infinite patience and devotion, Dr. Howe succeeded in unlocking the mind of this poor deaf mute until she became mentally alert, and developed into a well-educated woman.

Soon after the founding of the Perkins Insti-

tute, those at New York and Philadelphia were established in 1831 and 1833, respectively; and then, as the duty of the public towards these defectives began to be recognized, came the state institutions, which now exist in nearly every state.

The education given is at first similar to that of the ordinary common school, accompanied by manual training and gymnastics. Special training is also afforded in some handicraft, or for some professional or business occupation, according to the talent and ability of the pupil. Music and pianoforte tuning have been found peculiarly adapted to the blind, and some have attained eminence in the latter, as, for example, John Stanley, who was an organist at the age of eleven. The aim in the education of the blind is, first, to establish hope, the hope that in spite of their grievous handicap, they can attain a man's standing in the world, for hope stimulates endeavor; second, to give them a general common education; and third, a practical or technical education so that they may become self-supporting. It speaks well for the altruistic spirit, and as well for the economic sagacity of this country that it is so fully and liberally accomplishing this self-imposed task.

Culture and humanity are not necessarily close companions. We still seek philosophy from Plato and culture from ancient Roman literature; but it was a custom of both Greeks and Romans, to throw their deaf into the river and destroy their defectives,—a rather merciless eugenic method of ensuring a sturdy race. The deaf were regarded as being in the same class as idiots. Saint Augustine declared that the deaf could have no faith, since "faith comes by hearing only." A century ago even, the deaf were practically outside of human thought and activities, and for a long time were regarded as an exceptional class, like the peculiar silent folk Rip Van Winkle encountered in the mountain hollow. Various legal enactments were made indicating this attitude towards them, such as exemption from poll and other taxes; forbidding them from making wills, unless their intention was declared in writing; the appointment of guardians for them, etc. As time went on, however, and civilization advanced, it was found that these people of silence were mentally sound, and by education could be developed into rational beings.

At the beginning of the last century schools for the deaf began to be founded on the Continent and in England, and in 1816 Gallaudet established the first school for the deaf in America, at Hartford, called the Connecticut Asylum. At the present day, liberal state provision is made for the education of the deaf and the deaf and dumb, and after they have received their education they are regarded as are any other members of society, and are considered able to look after themselves. As wage earners they compare well with the average of the rest of the

population. According to the census of 1910 there were 43,812 deaf persons in the United States, 90% of whom became deaf before the twentieth year, and nearly three-fourths under five years of age. From three-fifths to two-thirds are caused by accident or disease, mostly from the latter, of which scarlet fever and meningitis are the most frequent causative factors.

In every state except New Hampshire, Nevada and Wyoming there are public institutions for the education of the deaf, and these three excepted states, on account of their small population, make provision at public expense for their deaf in other state schools. Some states have more than one such school. It can be said that every deaf child in the United States under twenty-one years of age is now given the opportunity of an education and afforded maintenance in a state institution. In a few of the Eastern states the institutions are in private hands but receive state assistance and are subject to public supervision. In ten states there are dual schools for the deaf and blind.

W. H. Addison of the Mosely Commission of England, who visited this country in 1907, testifies that "the care and instruction of the deaf seems everywhere to be regarded as one of the first duties of the state, and in the equipment of her schools for the deaf, America far surpasses Great Britain."

At the close of the year 1910 there were 10,543 inmates of deaf and dumb institutions, of which 5712 were able to speak, and 4831 were dumb. Of the whole number, 7054 were children, and of these 4172 were able to speak.

The two methods of teaching the deaf, as we know, are the sign and the oral methods, or a combination of the two. This education is not cheap, for it costs the state eight times as much to educate its deaf children as its hearing ones in the regular public schools, and four times as much in the day schools.

Besides the state institutional schools, in which about five-sixths of the deaf children are educated, there are day schools, which are a part of the public school system. These exist principally in the large cities, as in New York, Chicago, Boston and elsewhere. One of the first schools of this kind was the Horace Mann School, established in Boston in 1861. There are now in all sixty-five such schools. It has been found, however, that better results are obtained in the institutional or boarding schools, where the children reside continuously, than in the day schools.

In addition to all the states are doing for the deaf, Congress established at Washington in 1857 a college for the deaf and dumb, now united with the Gallaudet College and called the Columbia Institution. This is wholly supported by the Government.

A few of the aged and infirm deaf are found in the almshouses, but the total number is a little over 1%, thus showing that the great majority

of the deaf form a self-supporting part of the community and engage in almost all the various occupations and many of the professions.

Ancillary to the problem of the deaf and blind, is the medical examination of school children, by means of which these distressing defects in sight and hearing may, in some cases at least, be prevented: for by the early detection of infantile and infectious diseases, which are a prolific cause of deafness and blindness, and by timely treatment, such ultimate evils may be avoided. In Massachusetts the law requires the examination of the eyes and ears of the school children in all cities and towns of the state, the State Board of Education furnishing the test.

Another great class which may, I think, be included under the physically defectives are the tuberculous, although, of course, this incapacity is not always permanent, and the aim in the wide public provision made for them is not only treatment and care, but prevention. Quite every state has established one or more sanatoria for such sufferers and maintains them at public expense. The public appropriation for this purpose last year (1915) was \$14,500,000, and of this sum four states—New York, Pennsylvania, Illinois and Massachusetts—contributed over eight million dollars. Besides the sanatoria, special tuberculosis dispensaries are maintained by some states, as in Pennsylvania. In Massachusetts all cities of 10,000 inhabitants are required by law to establish and maintain such dispensaries. Municipalities, in many instances, maintain similar institutions under their boards of health, and likewise open-air schools or school rooms for the children with evidence of latent tuberculosis.

Besides sanatoria for supposedly curable cases of tuberculosis, consumptive hospitals for the incurables have also been established in some states, generally through local instrumentality, but with public supervision and state aid in maintenance. In Massachusetts the law requires all cities to establish such hospitals, and also towns when requested to do so by the State Board of Health. Municipalities have also taxed themselves to provide consumptive hospitals for their indigent incurables. Chicago, by the mill tax upon all taxable property of the city, has erected a great institution, which will provide for nearly a thousand patients. Boston has expended over a million dollars upon its Consumptive Hospital, and is constantly enlarging it. So of other cities. It is now proposed that by an act of Congress a special division of tuberculosis should be established in the United States Public Health Service, with an adequate appropriation, for the study and investigation of the tuberculosis problem. Thus it will be seen that legislation is actively engaged throughout the country in providing for its physically defective through tuberculosis.

Another incapacitating disease which in recent years has grown to large proportions is that

of the heart. For example, in New York in 1914 the deaths from heart disease increased from 74 to 169 per one hundred thousand, and other cities have had a similar experience. As with the child with latent tuberculosis, so with the child with slight or latent cardiac disease. Especial care in its education is equally necessary, and especial vocational training, so that it may learn an occupation adapted to its damaged heart. The wage-earner, likewise, with cardiac disease, would seem to deserve the same consideration as the tuberculous wage-earner. It would appear, therefore, that in the near future some public recognition and provision should be made for this class of defectives, if they continue to increase in the future as rapidly as in the past.

From the above it will be seen that the public in this country provides liberally for its blind, deaf and dumb, but very inadequately for its crippled and deformed, although the latter class outnumbers that of the two others combined. One cannot hope to make the lame man "leap as a hart," but by proper education his mind may be rendered alert, and by training the defective members made to do useful service.

### FRACTURES IN A BASE HOSPITAL.

By FREDERICK A. COLLIER, M.D., LOS ANGELES, CALIF.

(From the American Women's War Hospital, Paignton, England.)

THE American Women's War Hospital was opened in September, 1914, and in the course of 19 months from that time, till April 1, 1916, it has treated and discharged 2350 patients. It may be accepted as a typical base hospital, and the class of cases as typical of those cared for in all base hospitals, except a certain few of a specialized type. The cases treated are both medical and surgical; the total number of discharges comprised 836 medical cases and 1514 surgical cases, the large majority of the latter being wounded. Of this latter group, there have been 310 cases with fractures of one or more bones, or roughly, the cases with fractures comprised about one-fifth of all the surgical cases. A number of these cases presented more than one fracture problem, making a total of 327 fractures requiring treatment. In this list are included fractures of the skull, maxillæ and ribs, solely with the idea of showing the proportion of fractures occurring in these bones as compared with those in the rest of the skeleton, and the treatment of them will not be considered in this

paper except in a most general way. Their proportion in the following classification, however, is not a true one, as more recently there have been established special hospitals for the treatment of these groups of cases, and any which come to a base hospital arrive only through some oversight on the part of the transportation authorities.

Of these 327 fractures, 40 were simple and 287 compound, the latter caused by a missile of warfare in every case. In Table I a detailed list of the bones involved is given, the arrangement showing fractural entities as they occur. If we include the small bones of the hands and feet, we find that there are 159 fractures in the upper extremity in 113 in the lower; excluding these, however, we find that the number of fractures in the long bones is nearly the same in the two extremities,—90 in the lower and 85 in the upper,—the larger number of injuries to the hands than to the feet causing the difference when the entire extremity is considered.

**Missiles.** The compound fractures were caused by the following projectiles: 152 bullets, 86 shell fragments, 23 shrapnel balls, 9 by grenades or bombs, and not determined in 17 cases. The bullet wounds were perforating in 143 cases, the bullet lodging in 9 cases. The shell wounds were perforating in 64 instances and non-perforating in 22 cases. The grenade and bomb wounds were non-perforating and were marked by the multiplicity of fragments, in one instance 170 pieces of bomb being removed. In two cases of fractured femur in which the bullet lodged, there was a fine disintegration of the bullet after impact; this was observed only in the cases mentioned. In most of the perforating shell wounds, although the large

fragments had perforated, there were many smaller fragments of steel remaining in the wound, and in the perforating wounds caused by shrapnel balls, the course of the ball could be traced by the spattering of lead. The comparative velocities of the various missiles may be shown in a relative way by the frequency with which they lodged, varying from about 6/10% in the bullet, 25% with shell fragments, and 36% with the shrapnel ball, to nearly 100% with grenades and bombs. All projectiles that had lodged were removed except two bullets; one of these had remained in the head of the femur, and it was thought best not to attempt its removal at the time, but we have since ascertained that he has had a persistent synovitis of the hip joint since leaving the hospital, enough to incapacitate him, and viewed in the light of this history it would have been wiser to have removed the bullet. The second case was one in which the bullet lodged in the muscles of the back after perforating the arm, and has given rise to no symptoms. In many cases small fragments of shell were left *in situ*, although the main piece was removed and the wounds healed in every case.

**Infection.** In the 287 compound fractures there were 44 in which healing took place without infection, and 243 cases with sepsis of varying grades present. Of those wounds remaining clean, 30 were caused by bullets, 13 by shell and 1 by shrapnel ball, all wounds being perforating. The clean bullet wounds were those caused in the zone of perforation and showed the characteristic small, punctured, sealed wounds of entrance and exit; the clean shell wounds were all caused by small bits of shell casing, apparently never larger than 1 cm. in diameter, and had sealed wounds of entrance and exit. The single wound from shrapnel ball, in which aseptic healing took place, occurred in the arm, the fracture being an oblique one of the humerus, the ball glancing from the bone, and the wounds of entrance and exit being small and sealed. Of the infected cases, 238 were pyogenic infections caused by the staphylococcus, streptococcus, in many cases of an attenuated variety, B. pyocyaneus and members of the colon group. In the majority of the pyogenic infections the sepsis was of a low-grade nature, with a tendency to become chronic, with indolent granulations and sinus formation. There were only 5 cases from which the B. perfringens was isolated, but a routine culturing of wounds has been done only during recent months, and undoubtedly there have been many wounds from which the gas bacillus could have been isolated, but only in the 5 cases mentioned have there been any clinical signs of the organism. All were cases with extensive lacerated wounds with much destruction of tissues; crepitation, marked swelling and typical thin dirty grayish pus were present. Amputation was necessary in one case, the others recovering after free in-

FIG. 1.—"Butterfly" fracture of humerus from shell fragment, one week old.

FIG. 2.—Same as FIG. 1 four weeks later. Union firm with small fragments of shell in callus.

cision and drainage. The small number of grave infections may be accounted for in part by the fact that the cases are not transported until all virulent sepsis has subsided, the man usually being kept in some of the general field hospitals till he is deemed fit to travel. In all cases we have made a careful record of the length of time intervening between the times of injury and first dressing, the dressing in some more permanent hospital, and up to certain limits we have been unable to discover any relation between the virulence or absence of sepsis and the time intervening between reception of injury and application of dressings. Up to 12 hours the records showed nothing, but with longer lapses than this before any dressing was applied, the sepsis seemed to be more virulent, and in a certain small number of cases which did not receive a dressing for two or three days there was a decided increase in the severity of infection. However, this may be partly, if not wholly, accounted for by the fact that these cases were usually exposed without food or covering, with an attendant marked lowering of the general resistance. About 40% of the cases received their first dressings within less than 5 minutes; about 40% from this time up to 3 hours, and the remaining 20% from 3 hours up to several days. Of course no elaborate deductions can be made from this small number of cases, but in this series we found that the degree

and amount of sepsis was dependent on the character of the wound, the conditions under which it was received, and on the missile causing it, rather than on the character of the first dressing or the time when it was applied.

*Character of Fractures.* There were 12 incomplete fractures of the long bones, 7 grooving, and 5 perforating. The perforating fractures were caused, 3 by bullets and 2 by fragments of shell, and all occurred in the expanded spongy portion of the bones, 2 in the lower end of the femur, 2 in the upper end of the tibia, and 1 in the lower end of the radius. The types of fracture were usually of the classical varieties described, and those seen most frequently will be briefly enumerated. The fractures of the long bones by bullets were roughly divisible into three groups, those caused by perforation at short ranges giving the so-called explosive effect with the production of very fine comminution, the fragments being driven in the direction of the lines of force and scattered in the tissues between the bone and the wound of exit; there was practically no splintering or fissuring and the effect was more localized than one would expect. This type resulted in several cases in non-union, with a pronounced gap between the bone ends. It is associated with extensive wounds of the soft parts, especially the wounds of exit, and when infected the bone fragments lie exposed at the bottom of this open septic wound, and unite only under these most adverse

Fig. 3.—Double fracture of humerus. The upper caused by bullet at close range, compound with comminution. The lower a closed oblique fracture at some distance.

circumstances. This type of wound is shown in Figs. 5 and 10. The second type is caused at longer ranges in the zone of perforation, the bullet causing a characteristic fracture with fissures radiating from the point of perforation and the size of the comminuted fragments governed by the angles of these fissures, giving the so-called "butterfly" fracture. Fig. 1 shows this type, while Fig. 12 shows the fissuring present in a perforation at still longer ranges; these usually show very little deformity and good alignment. A third type resulted from impact of the bullet at terminal ranges, in the zone of confusion, causing fractures by contact; these were marked by the large size and small number of the fragments, and in most cases were oblique fractures with practically no comminution. The shrapnel balls having a comparatively low velocity caused fracture varying between the last two mentioned types, the oblique or a simple form of the butterfly fracture predominating. In neither of these types did the bone experience any loss of substance, and most of the fragments retained their periosteum. The fractures due to shell fragments were of all types, varying with the size, shape, velocity and angle of impact. They varied from simple perforations without loss of continuity to badly comminuted fractures with much loss of bone substance, and were often accompanied by large lacerated wounds with marked destruction of soft parts. In general, the fractures by shell

were marked by less severe bony destruction and greater damage to soft parts, the fractures by bullets showing greater bony destruction and less severe lesions in the soft parts. There were three cases in which simple fracture at a distance, caused by indirect violence, accompanied the compound fracture caused by direct violence. Two were of the humerus, the first a finely comminuted fracture of the shaft adjacent to the neck with a simple slightly oblique fracture of the shaft at its middle, shown in Fig. 3; the second was similar except the direct fracture was of the drill variety and incomplete, close to the joint, while again the simple indirect fracture was about the middle of the shaft. The other was a simple oblique fracture of the femur through the shaft just above the condyles, accompanying a fracture of both bones of the leg in their middle third. There was no history of fall or other accompanying injury. The first two were caused by bullets and the last by a shell fragment.

*Treatment.* The average time elapsing between time of injury and entrance to hospital in all cases was 15 days, but this is not a fair general average because it was raised very much by two convoys coming from the Mediterranean forces, most of whom were wounded at least a month before entrance, and one of them had been wounded three months previous to arrival. Usually the cases reach us about 7 or 8 days af-

Fig. 4.—Contact fracture of tibia by shrapnel ball. Ball has entire one half still in contact with bone. Typical symmetrical lines of fracture.

ter the injury. If, however, there was any large number of casualties, they are brought to us much sooner, reaching the hospital 48 hours after being wounded; one convoy reached the hospital 24 hours after the engagement.

The treatment may be roughly divided into two phases,—that received before admission, which consists principally of the treatment of early complications, virulent infection, secondary hemorrhage and shock, with the fracture receiving secondary consideration; the second phase comprising that treatment received after arrival in a base hospital, where the fracture receives primary consideration and complications

FIG. 7. Fracture of humerus by a bullet in the explosive zone showing free comminution which is sharply localized, a tendency toward formation of gap between bone ends and absence of fissuring.

are treated as they arise. The soldier receives his first-aid dressing as soon as possible after being wounded; this formerly consisted of an aseptic dressing, but more recently most of them are antiseptic in character, of a larger dimension than before. A few moments later in the dressing station, he is given another dressing, the wound is painted with iodine, anti-tetanic serum is given and fixation applied to the fracture. He is then transported through the routine of field hospital, casualty clearing stations, and ambulance train, to a general stationary hospital. Complications are treated as they arise, while passing through any part of this routine, by drainage, ligation, opiates and dressings. A serious case may remain at any point when deemed advisable. At the stationary hospital more permanent fixation is applied, drainage established for sepsis, and the patient is given an opportunity to recuperate. When deemed fit to travel, that is, when virulent sepsis has abated and adequate fixation applied, he is transported to the base hospitals in England.

The patients are transported in a variety of splints, most of them being made of wood and of a simple pattern. Some of the most common are the Thomas splint for femurs; a modification of this is often used for the humerus, wooden right angles for fixation of the elbow and simple wooden splints with foot rest for the leg. If the wound is inadequately drained, or when there is reason to believe that it has been imperfectly cleaned, the case is immediately operated upon, adequate drainage made, all fragments of missiles and clothing removed, the fracture reduced, and some apparatus applied that will give adequate fixation and at the same time allow the necessary dressings to be done. Missiles are removed at this time if they are readily accessible, and if no uninfected tissue has to be opened up in order to gain access to them. A greater effort is made to find shell fragments and shrapnel balls at this time than bullets, as they undoubtedly carry in enough clothing to render them a focus of infection. If the missile is not removed at this operation, it is removed after the sepsis has partly cleaned up, provided it is causing trouble of any sort; if not, it is left alone, but, as our records show, it has been thought advisable to remove most of them sooner or later. The principal septic focus is usually located between the bone and the wound of exit, along which track the fragments of bone are scattered, and it is here the principal drainage is placed. As regards the treatment of bone fragments, we have become more and more conservative about their removal. Fine fragments, loose in the tissues and bearing no relation to the correct alignment of the bone, are removed. Larger loose fragments, from which the periosteum has been stripped, are also removed, but all other fragments, that have at least a partial periosteal covering and any muscular attachment, are pushed back into rela-

tionship with the line of the principal fragments. If any sharp spicules are present on fragments adjacent to vessels, they are cut away. Occasionally the small fragments may extrude themselves later or their removal becomes necessary, but in case after case, one may see callus formation greatly assisted by the proliferation from these small fragments of bone, and in several cases a pronounced gap was entirely filled in by bony growth from these small fragments, as is shown in Fig. 8. The viability of these fragments, of course, depends a great deal on the virulence of the infection, but that they will live and proliferate in the presence of a pronounced sepsis there is no doubt. In fact, it would seem that these severely comminuted fractures offer particularly favorable conditions for early and solid union, since it has been shown by McEwen that the osteogenetic power of bone varies inversely with its volume.

For drainage we have used rubber or gutta percha strips in all cases, using in addition a soft rubber tube of small caliber for irrigation and for instillations of hypochlorous acid after the method of Carrel and Dakin. All drains are shortened and removed as early as possible, as it was found their prolonged use favored the formation of sinuses. Prolonged drainage is seldom necessary if the original incisions are properly made.

Plaster has been our chief method of fixation, with large fenestra for drainage with steel

FIG. 12.—Incomplete fracture of lower end of femur by shell fragment. Shows symmetrical arrangement of bone along walls of wound of exit.

arches incorporated in the cast to provide support over these points. It has been very satisfactory when good plaster has been obtainable and when a proper extension table is available, but lacking these and in inexperienced hands, other methods are advisable. We have been using a modified Balkan splint which is a suspension frame with extension applicable in all directions. It is adaptable for both arms and legs, the arms being suspended either without support or in abduction in a modified Thomas splint. The legs and thighs are slung by means of some anterior or posterior moulded splint and extension applied directly to the leg. The patient may move about in bed a certain amount, and dressings are very easily done as the limb is always accessible. For fractures with simple dressings the ordinary forms of apparatus are applicable with occasional slight modifications.

For the after-treatment of these septic fractures, we have used hypochlorous acid solution 1:200, and more recently hypertonic saline solution has been tried in a number of cases. Both methods have given very satisfactory results, and thus far we are unable to say which is preferable. Both solutions are used either as a constant irrigation in foul wounds with much necrotic tissue present or as hot dressings changed every two to three hours with intermittent irrigations; after the wound has been cleaned up, some simple form of dressing is used. In the wounds with large open areas secondary suture is done as soon as possible, not with the idea of closing over a septic bone focus, but to diminish to a minimum scar formation and disabling contractures.

Bone plates have been used in fourteen instances of compound fractures and with what

FIG. 13.—Fracture of tibia by bullet at foot, comminuted by absence of comminution, slight displacement and the tendency to formation of long sinuses.

we consider good results in some cases. In the light of this experience with them we believe that there are a certain few septic open fractures in which the use of the bone plate is justifiable. They were applied only in those cases in which malposition was still present after all external methods of fixation had been tried. The plates were put in with the knowledge that they would have to be removed later and we believe the results were better in spite of the prolongation of the sepsis and the increased necrosis at site of the screws than could have been obtained by allowing union to take place in malposition with a corrective operation after sepsis had cleared up. The plates undoubtedly do retard or inhibit callus formation at their site, consequently they should be removed as soon as there is enough callus present to fix the bone ends in position, and should never be left till firm union occurs or till the plates are loosened or extruded. As one is working with bone of very low vitality, it is more necessary than ever to operate with a minimum of trauma. One of the cases proved most instructive, showing clearly the absence of regeneration around the bone plate. It was a case with a fracture of the lower end of the femur and an amputated leg. The femur had been plated, and later, after union had taken place, it was found necessary to do an amputation of the thigh because of contraction of the hamstring muscles interfering with the wearing of an artificial leg. The specimen obtained showed a firm symmetrical callus with firm union except at the site of the plate, and for 1 cm. on all sides there was a total absence of all callus, with devitalized bone present only at this point. There was non-union in one case of compound fracture of the lower end of the femur, to be mentioned in detail later.

Twenty amputations were done in the entire series, of which eight were performed in the field hospitals before entrance. They were: one of the arm for fractured humerus with severed brachial artery, one of the thigh for comminuted fracture of the lower end of the femur and septic knee, another of the thigh for fracture of both bones with a septic knee joint, three of the leg for infected shell or bomb wounds, with much loss of bone, one of the forearm for fractured both bones and severed arteries, and two fingers for mutilating wounds. There have been twelve done here,—eight fingers, two of the thigh, one for non-union with osteomyelitis, the other already mentioned for contracted muscles in a stump, one of the leg for fracture of the tarsal and metatarsal bones with toxic absorption, and one of the forearm for a fracture of both bones, with gas bacillus infection. All the six major amputations done in field hospitals were done by the circular no-flap method of Fitzmaurice Kelly, and in five of them reamputation was necessary because of osteomyelitis in the bone ends and retracted flaps. The simple fractures were all of the types usually seen, and their treatment

FIG. 14.—Fracture of humerus by a bullet with comparatively low velocity which has lodged in chest wall. The fracture is of the "butterfly" type with a slight rotation of the lower fragment.

did not differ from that ordinarily used. Three of them were bone-plated, the wounds remaining clean and the plates remaining in position.

*Complications.* The patients, with very few exceptions, were strong, healthy young men, and the ordinary medical complications were very rare; there was no pneumonia in the entire series, and syphilis was not suspected in a single case. Many of them presented multiple wounds of the soft parts of more or less severity, which, while seldom serious, complicated the application of apparatus.

Two cases of tetanus appeared, both in men with compound fracture of the leg. The first had an incubation period of two weeks in a man who had not had a prophylactic dose of serum, ran a mild course, was treated by intravenous and intrathecal injections of serum and recovered. The second was a case of the so-called latent tetanus appearing two months after injury. Seven weeks after being wounded he was given ether and the position of leg corrected; one week later tetanus of a mild character developed, reacted quickly to anti-tetanic serum given subcutaneously and made an uneventful recovery. (Reported by Dr. D. P. Penhallow in the *Lancet*, Feb. 26, 1916.) There has been one case developing erysipelas in the series.

*Necrosis.* As has been said, the treatment in many cases resolved itself into that of a fracture complicated by a localized necrosis, and it

is this complication that has proved one of the most difficult to deal with. There were two varieties of necrosis, the first being the necrosis resulting from the trauma of the injury giving rise to devitalized fragments, which when not removed at the preliminary operation later extruded themselves or had to be removed. This is the comparatively small price one pays for the conservative treatment of comminuted fragments already mentioned. The other variety of necrosis was due to infection acting on what at the time of the original operation was viable bone. Of the 243 cases with infected fractures, operation was found necessary for the removal of sequestra in 115 cases, or in nearly 50% of the cases, and often multiple operations were done for this purpose. They were done for the most part after the callus formation was well established, and a conservative plan was still followed, endeavoring to wait until the necrosed fragments had spontaneously separated from the sound bone, then removing them, with care not to traumatize any of the surrounding bone; the indiscriminate and vigorous curetting of these areas, often causing the formation of distressing cavities, very hard to close in, and infection of healthy bone. Often primary union was obtained after excision of the sinus, removal of the sequestra and sterilization of the cavity. In eight cases in which there was a fracture through the head of the humerus, excision was necessary in 6 cases, 2 with little comminution were reduced and union took place. The plan adopted in regard to the treatment of

the head was the same as that mentioned above, any loose pieces were removed immediately, and excision, complete or partial, done after it was seen that there had been established a line of demarcation between the dead and living bone. Of 4 wounds of the head and neck of the femur, excision was necessary in one case.

*Non-union and Delayed Union.* There were two cases of delayed union, one a simple fracture of the shaft of the humerus in good position in a healthy man. At the end of three months there was a very slight callus with no stiffening; blood was injected into the callus, and firm union was present 6 weeks later. Another was a transverse fracture of the proximal phalanx, caused by a knife; no union was present after eight weeks, so friction was made between the fragments, and union soon took place.

Seven cases with non-union occurred, one a case already mentioned in a middle-aged man with a transverse fracture in the lower third of the femur, with a foul discharging wound. He had been treated two months in a field hospital before entrance, and was very anemic, debilitated and somewhat toxic. Fresh drainage was provided, and for four months extension maintained the bone in good position, without any union resulting. A bone plate was then applied, and at the expiration of ten weeks, no union having resulted, an amputation was done, and absolutely no evidence of repair was found, due probably to the extensive osteomyelitis and necrosis in the bone ends. There were three cases somewhat similar in type, two of the radius and one of the ulna, in which there were long gaps between the fragments, varying from four to six inches in length. They were all the type of fracture caused by bullets at short ranges, with very large wounds of exit, so that the finely comminuted fragments were lying in the open septic wound, and in one case all bone fragments were removed by the surgeon. This type of wound, with the accompanying bone conditions, is shown in Figs. 5, 6, 9, 10, 11. These cases were discharged with this disabling deformity, but it is conceivable that a bone graft might be tried in such conditions, as has been done in the following cases. One, of the humerus, with a septic butterfly fracture of the lower end of the bone, in which all fragments were removed, leaving the typical pointed ends to the upper and lower fragments, with a gap intervening. (See Fig. 18.) It healed eventually, and after three months an inlay graft from the tibia was inserted, with a rapid regeneration of the graft and firm union. (See Fig. 19.) A similar procedure was done to a tibia with a gap of 1½ inches, and union resulted. The other case of non union was a simple transverse fracture of the humerus that had been plated in very poor position before arrival here. No union existed and the plate was loose. The plate was removed, an inlay graft inserted and convalescence was uneventful. Before do-

FIG. 16.—Perforated bullet wound of wrist with marked disorganization of joint.

ing any clean corrective operation on bone, we have waited till three months after the sepsis has disappeared, and although this may be excessive we have had infection occur, from what was undoubtedly latent sepsis, in operating before this length of time had elapsed.

*Secondary Hemorrhage.* This has occurred only three times in the series while cases were in the hospital,—two from perforating branches of the femoral artery and one from the palmar arch. From the records of other hospitals we were able to obtain information about three cases in which hemorrhage occurred before entrance, one from the brachial and two from the posterior tibial arteries. In one of the latter cases amputation was done. All others were controlled by packing and ligature.

*Nerve Lesions.* In only eight cases was there recorded any serious nerve injury. One of these, an injury to the brachial plexus with paralysis of the arm, followed a comminuted fracture of the outer end of the clavicle. A large bone fragment was found pressing on the plexus and removed, after which function gradually returned, and in two months' time was nearly normal. There were three musculo-spiral paralyses, all occurring with fractures in the lower third of the humerus. In two of these there was found complete division of the nerve, and suture was done in both cases, and in one case the nerve was found caught in the scar and freed. In two instances the external popliteal

nerve was caught in scar with attendant paralysis. Neurolysis was done in both cases. Two radial paralyses were present, one from a severed nerve which was sutured; the other recovered spontaneously during two months following the injury. The median nerve was divided at the wrist and was sutured. We are unable at this time to give a report on the results in these cases as they all left supervision before any definite conclusion could be reached.

*Fracture in Joints.* These were frequent, and were usually attended by disabling and disappointing results. There were 13 fractures into the shoulder joint, 3 closed, the latter recovering with good results. Ten were compound and infected. In 6 of these complete or partial excision of the head of the humerus was necessary, resulting in 2 flail joints and 4 ankylosed joints, and in the 4 remaining cases it was not necessary to remove the head, and a good result was obtained in one case with but slight limitation in abduction, while in the others there was pronounced limitation of motion in all directions. The elbow was involved in 10 fractures, 3 closed, of usual types, and with good function resulting. Seven were compound and septic, resulting in 5 complete ankyloses, and 2 with motion through about half the normal area. The wrist was involved 5 times, all infected, resulting in 3 complete ankyloses and one partial ankylosis and the other having only very slight limitation of motion. The hip joint was opened by septic fractures in 3 cases, 2 of which re-

FIG. 17.—Fracture through head of humerus with removal of portion of head. Shoulder ankylosed in this position resulting in a useful arm.

sulted in complete ankylosis, the other resulting in very slight limitation of motion but with persistent synovitis. There were 4 septic fractures involving the knee joint, resulting in one useful knee and 2 partial and 1 complete ankyloses. There were a number of simple fractures into the ankle of the customary types and 5 compound fractures, 4 of which resulted in nearly complete ankylosis and 1 with only slight limitation of motion.

*Contractions and Ankyloses.* As has been shown, the fractures into joints were followed by a large percentage of disabling ankyloses, but aside from the ankylosis following this type of injury there were those due to other causes. The two principal additional causes were sepsis in the periarticular tissues or in muscle groups and tendons with cicatricial contraction and immobilization of these structures, causing a consequent immobilization of the adjacent joint; second, prolonged immobilization in apparatus. In certain cases with perfect joint surfaces there would be an absolute fixation of the part in a flexed position, due to contracting scar tissue. These were usually cases that had been under treatment for long periods in field hospitals under unfavorable conditions, and their correction offered some most interesting and perplexing problems. The true ankylosis resulting from infected fractures into the joint presents an almost hopeless problem in a military hospital, where time is limited and patients pass out of supervision after leaving the hospital. An attempt has been made in this group of cases to ankylose the joint in the position most favorable for function. For the shoulders we have found the most useful shoulder, for a man who must do manual work, to result from an ankylosis at about 45° from the body, this giving the greatest range of scapular motion, the arm inclining slightly forward from the perpendicular. The flail joints, while of course not resulting from excisions of the classical type, but being done as circumstances permit, give poor functional results; the motions were of fair range but strength was lacking. They were more useful, however, than an ankylosis of the shoulder with the arm near the body, as unfortunately occurred in one case. The elbows were ankylosed at slightly less than a right angle, and the wrists in dorsiflexion. That group of disabilities resulting from contractions may be nearly obviated by the use of correct apparatus from the start. There is a noticeable tendency among inexperienced men doing military surgery to treat each case as two problems, the first of healing the wound without regard to function, and second to secure function if possible. The amount of contraction from the large wounds is deceptive, and always greater than anticipated. Very early massage, and when possible, early passive motion, is instituted on all fractures in an endeavor to minimize the number of ankyloses and contractions from prolonged immobilization.

*Results.* Although we have not been able to follow the cases after they leave the hospital, as this is manifestly impossible while the war is still in progress, yet we have been able to ascertain a certain number of facts concerning the end results. No one man or group of men is responsible for the results, the personnel of the staff having experienced frequent changes, and no one fixed policy of treatment has been pursued since the origin of the hospital; the results should then be a fair general average and comparable to any general military hospital, in which changes of the staff are frequent.

In general the following disposal of a case may be made. He may be sent to duty, in which case he must be able to resume active duty at the expiration of a short furlough, or he may be sent to a convalescent home, in which case he must be able to resume duty in a certain number of weeks and to require no more surgical procedures,—only simple dressings are done here,—and finally he may be invalided out of service if he is not fit for duty, in which case all wounds must be healed and no more surgical care required. A man may be invalided for a certain number of months and then return to the army, but this very rarely occurs. A man is never invalided until every effort has been made to secure the best possible function, as the pension given in general varies with the functional capacity of the individual. In speaking of results, we will have to base the computations on the total number of cases discharged and not the total number of fractures.

*Disposal.* There have been four deaths in the series, but these occurred in those specialized groups of fractures that we have only mentioned and not discussed. They were 3 fractures of the skull and 1 of the spine. There were no fatalities occurring in cases with fractures of the long bones. Of the remaining 306 cases, 137, or 44.2%, have returned directly to duty, 75, or 24.2%, have been sent to convalescent homes, to return to duty in a short space of time, and 94, or 30.1%, have been invalided from the service. Grouping the above, we find 68.4% returned eventually to the army and 30.1% were invalided from service. These figures would be somewhat lower if we excluded the fractures of the skull; as according to recent rulings any man with a trephine opening in the skull is invalided, no matter what his functional capacity may be. The conditions present for which the men with fractures in the extremities were invalided were roughly grouped in Table 2.

It is instructive to note that the majority of the cases were invalidated because of lesions affecting the joints, showing the necessity for careful orthopedic supervision, and is a small indication of the opportunities for orthopedic work in a hospital of this kind.

**Function.** In estimating the function at the time of discharge, we have taken the following approximate standard: Good function, to indicate that the individual will be able to resume duties in the army or in civil life, without any diminution in his efficiency. Thus some of the invalidated men may be considered as having good function, although they might not at the time of leaving be unable to do a long march, and as a consequence would be invalidated.

Fair function, to mean a result that will enable a man to resume his usual manner of livelihood, with a somewhat decreased efficiency, but one who will not become an economic burden to the state.

By poor function we mean that the man is incapacitated for active work in civil life, and without some complicated apparatus, for example, an artificial leg, will have a reduced effi-

FIG. 19.—Same case as FIG. 18 three months after application of an inlay graft from tibia held in place with bone pegs.

ciency and will get a pension from the state for life.

Judging by the following standards, we find that there are 219 men with good functions, 46 with fair function, and 41 with poor function. This result is not markedly different from that given before when considering the disposal of the cases, but it shows what proportion will get pensions for life, and translates the results from military terms to those of civil life.

**Time in Hospital.** In order to get some idea how much longer these cases needed to be under supervision than cases in civil life, the length of time elapsing from the time of injury and the time of discharge from surgical supervision has been computed for each fracture, and a general average taken for each group. The averages thus obtained of course do not represent the time required for union, but show the length of time that each group of fractures required surgical supervision, and thus represents in a way the tax put upon the medical service of an army by injuries of this variety. These averages are given in Table 3.

This table also gives the number of cases in each group who were sent to duty; this includes those sent to convalescent camp who return very soon to duty, as explained, those invalidated, and the deaths. The average time elapsing in each group from time of injury till discharged from surgical supervision is given, expressed in days. On cases with two or more fractures the case is placed under the group of the more im-

portant fracture, and the lesser fracture is not included. The totals are expressed in terms of individuals, and not of fractures, as was the case in Table I.

I wish to express my thanks to the Executive Committee of the American Women's War Hospital and to the Chief Surgeon, Dr. D. P. Penhallow, for permission to use the records of the hospital, and to the other members of the Staff for their courtesy in allowing me to follow the progress of certain of these cases in their wards.

## SPECULATIONS REGARDING THE PANCREAS AND METABOLISM IN DIABETES.

By HUGH P. GREELEY, M.D., WACKESHA, WIS.

To the great mass of literature about diabetes it is almost presumptuous to add anything unless it be supported by all sorts of experimental and clinical evidence. The following ideas, however, though unsupported at this time by such evidence, are in the nature of a preliminary statement, and so I venture to present them if only for discussion and refutation.

It is certainly not over-stepping bounds to adopt the premise that diabetes mellitus is a disease of the pancreas. It is also true to say that in degree and severity it is most variable. The ordinary classification of von Noorden into mild, moderately severe and severe types is recognized as arbitrary since there are all gradations and they merge into each other.

We are all born with different heritages. Each organ in the body is destined to have a certain maximum functional "horse power."

By care in breeding and environmental conditions, functional capacities might be increased. Careless breeding and wrong environmental conditions, no doubt, diminish them.

The work of the pancreas, or of its internal secretion is almost as continuous as the heart beat, and only ceases entirely with death when all metabolic activity ceases. Almost all organs of the body are provided with great reserve power. One-half a lung if intact is enough to support life; one kidney is ample; the heart has five or six times as much reserve as it is called upon to exert under anything but the most severe and sudden strain. Experimentally, likewise, one-eighth of a pancreas or less is usually sufficient to prevent the onset of diabetes.

Undoubtedly we are all born with different pancreatic functional capacities varying in the same way that our mental capacities vary, and subject to change through heredity, overwork or disease. Some have less, some more reserve power; some people may have larger and better equipped islets or more of them, others smaller, poorer or fewer. Our pancreases are "geared" to a certain maximum metabolic activity and endurance.

It is wholly reasonable to suppose that in man as well as in experimental animals the functional capacity of the pancreas must be reduced between seven-eighths or nine-tenths before true diabetes ensues. The reduction of functional activity can be relative or absolute, functional or organic, and as varied in its causal relationships as failure of cardiac compensation. In other words the relation of functional capacity to total metabolism is a mathematical one. Supposing the normal figures are represented by  $\frac{4}{5}$ ths pancreatic capacity, covering a metabolic activity of 60 kilos body weight: If the body weight is increased by 40 kilos, the total metabolism requirement would be increased and the functional capacity relatively reduced 66%. The amount of reserve power would determine its sufficiency. Failure of compensation would mean diabetes.

In obesity a very similar condition is present. Obesity may be a condition of abnormal metabolic function resulting in the abnormal storage of energy rather than in its normal combustion, and is closely related to diabetes. An enormous increase in body weight so increases the total metabolism, that the pancreas succumbs to the strain and diabetes ensues. Obesity is only one condition where total metabolism is increased and pancreatic function is disturbed. Fever and Graves' disease are often associated with glycosuria, and if diabetes is preëxistent, it is greatly aggravated, possibly by the greatly reduced relative functional capacity of the pancreases. Hence the fatality of infections in diabetes?

In an opposite way influences which reduce or retard metabolic activity benefit diabetes. It has been known for a long time that morphine

derivatives will drive out the last traces of sugar when only traces remain. May not this be due to a reduction of metabolic activity and a temporary establishment of pancreatic compensation?

The severity of diabetes follows a steadily declining curve as age increases. It is so mild in old age that for years the name diabetes has been denied these cases and glycosuria substituted. The curve of basal metabolism coincides exactly with the curve of severity of diabetes, being greatest in infancy and childhood and least in old age. The severity of a mild case of diabetes is at once increased by the incidence of any accident increasing basal metabolism (fever, infections, goitre). Glycosuria in old people is suddenly true diabetes in the presence of an infection.

The remarkable variations in sugar tolerance in the same diabetic individual has been suggested to argue the functional character of the disease. It does not necessarily follow, however. Severe organic disease in any organ is capable of the same variation of function under the sole influence of rest. Again we think of cardiac compensation. Surely the amount of almost perfect rest afforded by the Allen fasting treatment is ample means of restoring a considerable degree of tolerance, and it is noticeable that the more rapidly the carbohydrate tolerance has been broken down, generally, the more rapid its recovery; the slower, the more difficult. In one case we may be dealing with fatigue; in the other, exhaustion of an already weakened organ. Of course there are other factors which increase tolerance as well as rest,—factors which promote better combustion of energy, mental preoccupation and muscular activity. However, the remarkable success of the Allen fasting, I believe, is largely due to this element of relatively absolute rest. Rest is the *raison d'être* for almost all medical treatment of chronic metabolic disease. That variations in the diabetic condition point to the functional nature of the disease in large majorities of the cases is insupportable, since the most prolonged periods of rest and freedom from all signs of the disease have not resulted to date in many cases of authentic, complete and permanent restoration of pancreatic function; only a relative compensation of function which prevailed only so long as the amount of work was regulated to the power of the pancreas for that work.

The proof of theories must be left to the experimental worker. Theories are merely the results of deductive reasoning. However, some of the clinical facts which seem to support these views are these:

*Diabetes in obesity.* Cases are so frequent that individual case histories do not require citation. In every man's experience there have occurred typical cases like the following: A man of 275 pounds develops diabetes with acute symptoms: polyuria, polydipsia, loss of weight, perhaps acidosis. His case seems acute and

severe. After four to six months without treatment he may lose 100 pounds, and his diabetes seems to suffer an automatic remission. All the acute symptoms have disappeared. Nature has attempted a crude cure. By reducing bulk and total metabolism, an overstrained, weakened and insufficient pancreas has become relatively vastly more sufficient to its job. However, infection, which would immediately accelerate metabolism, would instantly cause exacerbation of all acute symptoms and render the case severe again.

It is equally interesting to observe the opposite in children. Among our cases are many children, who on first examination seemed mild cases without acidosis, and with relatively high carbohydrate tolerance. A typical example is case No. 876, a boy of six, who in 1912 weighed 45 pounds and had a sugar tolerance of 30 grams. He has been kept wholly sugar free, with rare accidents, and yet today, at the age of 9, he weighs 60 pounds and his tolerance is about 20 grams. His growth and metabolic requirements have increased over 30%, and his sugar tolerance has decreased a like percentage. This story might be reproduced many times in our series and seems to show that diabetes is a progressive disease in children, but closer analysis shows that it is really the child who is progressive, and not the pathological condition. The most painstaking pathological examinations have failed to reveal definite organic lesions. This probably argues an inborn insufficiency of the Islands of Langerhans functional or organic (numerical?). Pathological examination would not be complete unless size and number of islands were taken into account.

Von Noorden and others have drawn attention to the fact that familial diabetes tends to occur at earlier ages in consecutive generations. If the age of onset in the first instance was sixty-five, the inherited functional capacity would be relatively lower at an earlier age in the next generation because of the greater metabolic demands at this earlier age, and would thereby explain the observed phenomenon.

Provided these theories are sound, it would be possible to predict to a mathematical certainty the future course of carbohydrate tolerance in children with diabetes. Given the age, weight and carbohydrate tolerance, the expected normal rate of growth and increase of metabolic activity would proportionately decrease the carbohydrate tolerance till it became zero. Modern treatment offers hope for children never before conceived. Intercurrent infections are the pitfall.

It remains to be proven whether continuous successful management results in actual regeneration of power in the pancreas. The thyroid and liver are regenerative organs. The pancreas up to the present time has seemed not to belong to this group.

## Clinical Department.

### A REPORT OF THREE CASES OF TYPHUS FEVER.

By M. G. BERLIN, M.D., DORCHESTER, MASS.

THE cases here reported occurred at the Boston City Hospital (Third Medical Service) during the writer's period of internship.

The fact that typhus fever is a rare disease in the United States seemed sufficient reason for reporting these cases.

**CASE 1.** H. K., a single man, aged 23, born in Russia; arrived in this country ten days previous to onset of present illness. His family history was not remarkable. He had typhoid fever ten years ago and was sick then for four weeks. His habits were good and he denied venereal disease.

He was admitted to the Third Medical Service, Boston City Hospital, May 14, 1914. The onset of his present illness was very acute, with severe headache, chills and fever. There was no cough or expectoration, no dyspnea or palpitation. The appetite was very poor. There was no vomiting or diarrhea. No pain in the abdomen or chest. Micturition was normal; urine concentrated and diminished in amount. He said that he had had several small nosebleeds in the past ten days. He was well developed and well nourished. Conscious and rational, but slightly stuporous; his temperature was 104° F. The pupils were equal, regular, and reacted promptly to light and distance. The teeth showed marked sordes, and there was slight pyorrhea. The tongue protruded in the median line, was tremulous and showed a moderately thick dry white coat. The throat was moderately congested. The neck was not rigid. There was no glandular enlargement. Heart: the area of dullness extended from 3 cm. to the right of the median line to 9.5 cm. to the left apex in fifth intercostal space, just inside the left nipple. Action rapid, regular, and sounds of good quality; P>A, no murmurs. Lungs were resonant and breathing normal. Abdomen was level, soft and tympanitic; no tenderness, masses or spasm elicited; the liver and spleen not made out. The knee jerks were present and active on both sides. The skin showed a subcuticular eruption, petechial in character, with occasional dried-up vesicles. The individual spots were from 1-3 mm. in diameter. This eruption was over the abdomen, chest and back; it was not present on the face or the extremities.

Urine examination negative.

White blood count, 6500.

Blood culture taken.

*Progress of Case.*—May 16. Rash is more intense and is now present on the arms and legs. Temperature and pulse remain high. Spots in most instances do not disappear with pressure; petechial in character. Widal reaction negative.

May 18.—Temperature remains high. Rash unchanged. There is marked stupor. Pulse rapid and weak. Slight cyanosis and dyspnea appeared. Slight cough appeared, and there were numerous moist râles in both bases. Cardiac stimulation was instituted.

May 20. Condition unchanged. Prostration is

marked and patient is in intense delirium. Widals persistently negative. Blood culture negative.

May 22. This afternoon, on the 17th day of the disease, the temperature dropped to normal, by crisis; the pulse and respiration also dropped. General condition is somewhat improved. Rash is fading. The patient shows marked emaciation. Subsequent to the last note the general condition improved so rapidly that the patient was able to sit up by June 10, and was discharged well on June 18, 1914.

I happened to meet the patient about three months ago, and he appeared to be enjoying good health, having gained ninety pounds since he left the hospital.

**CASE 2.** Sarah B., aged 34, admitted August 2, 1914; said to have been only ten days in this country. Her father and one brother died of cholera morbus. Her mother and three brothers are living and well. Her husband and three children are living and well. No miscarriages. No chronic diseases in the family. She is said to have had measles, varicella, scarlatina, and mumps when a child. Had typhoid fever at ten years; sick then for seven weeks. Catamenia began at 16 and has been normal since. Her habits were good.

Present illness began abruptly eight days ago, two days after her arrival in this country, with general malaise, followed, on the second day, by chills, fever, severe headache and vomiting. Some nosebleed. No cough or expectoration, no night sweats. No urinary or intestinal disturbances.

Physical examination showed a fairly well developed and well-nourished woman, markedly prostrated. The face was flushed. Pupils normal. Teeth poor. Tongue coated and tremulous. Throat was markedly inflamed; no exudate or membrane seen. Heart was normal. Lungs showed many medium moist râles, but there was no impaired resonance. The abdomen showed tenderness over the epigastrium and over the spleen. The liver was felt 2 cm. below the right costal border. The spleen was palpable. The skin over the abdomen, chest, arms and legs showed a fine subcuticular mottling, largely petechial.

*Progress of Case.* The temperature remained elevated for four days after admission, when it dropped to normal by crisis. The vomiting persisted for three days. Patient was only mildly delirious at times. Widals and blood cultures negative. Condition improved rapidly, so that patient was allowed to sit up on the 12th, and discharged well on the 15th day of August, 1914.

**CASE 3.** A. D., married man, 29 years of age. Clerk in a pawn shop. Admitted on July 25, 1915. Family history irrelevant. Past history: measles, mumps and scarlatina when a child. Pneumonia when at Rutland State Sanatorium four years ago. Had many attacks of hemoptysis seven years ago. In Rutland off and on since 1910. Discharged "improved" on May 1, 1915. His habits were good and he denied venereal disease.

Present illness began rather abruptly six days ago with chills, fever, and severe headache. He began to vomit three days ago and still continues to do so. Has also had generalized abdominal pain, colicky in character. Appetite poor and bowels costive. Sleeps poorly. No nosebleeds. No cough or expectoration. No night sweats. No pain in the chest.

CASE 1.

Physical examination revealed a well-developed and well-nourished man, conscious and rational, very restless and uncomfortable because of some abdominal pain. Lungs showed impaired resonance throughout, especially at both tops, front and back. Breathing was broncho-vesicular throughout—especially marked at both tops. No râles heard. No friction rubs made out. Abdomen was distended, soft and tympanitic; there were no masses, tenderness or spasm. Liver and spleen not made out. Extremities negative. Skin showed a fine macular eruption over chest and abdomen, resembling rose spots, but much more abundant, and did not disappear on pressure.

July 26. Patient markedly prostrated, temperature high, pulse rapid, vomits his food.

Urine, fever urine.

Wassermann on blood negative.

Blood culture negative for typhoid bacilli.

Sputum showed no tubercle bacilli.

Widal reaction negative.

July 27. Temperature rose to 104°F. this afternoon. Patient somewhat delirious. Rash persists. Widal again negative.

July 29. Temperature still elevated but patient looks a little brighter, says he feels somewhat better. Rash appears to begin to fade. Widal negative.

July 30. Temperature dropped to normal by crisis, early this morning, and patient looks much better. Rash fading decidedly.

Condition improved rapidly. Patient was allowed to sit up on the first of August and discharged well on August 4, 1915.

#### POINTS OF INTEREST.

1. The diagnosis in these cases was made on the suddenness of the onset, negative blood cultures and persistently negative Widals, the early

CASE 2.

mental symptoms and the early marked prostration; the distinctive subcutaneous eruption and the termination by crisis. The diagnosis in all these was confirmed by Dr. Edwin H. Place, and, in the last case, also by Drs. Mahoney and Shea of the City Board of Health.

2. A very interesting point was brought out by Drs. Mahoney and Shea in the last case: the patient, who was a clerk in a pawn shop, was handling old clothes brought in by sailors, hence the great possibility of the source of infection.

3. The first two cases apparently contracted the disease on board ship, as they were both only a few days in this country when they took sick.

4. Patients were kept in the general wards and no cross infections occurred. The attendants, as well as the doctors and nurses, all

CASE 3.

escaped infection. This fact goes to show how much good hygiene and sanitation will do towards controlling a highly contagious disease like typhus fever—as has been so well demonstrated in the recent typhus epidemic in Serbia.

5. It is worthy of note that there were two male patients against one female, and that the latter had a comparatively mild attack,—facts well recognized in most cases reported.

6. It is remarkable that for years previous to this series there has been no case of typhus fever admitted to the Boston City Hospital, while these three cases appeared within the short period of fourteen months.

I desire herewith to express to the Visiting Physician of the Third Medical Service, Dr. John L. Ames, my grateful appreciation of the opportunity to record these cases.

## Medical Progress.

### REPORT ON DERMATOLOGY.

By JOHN T. BOWEN, M.D., BOSTON.

#### THE MODERN TREATMENT OF BURNS.

DR. TARNOWSKY<sup>1</sup> bases his article on the experience obtained by treating several hundred electric burns, together with some experimental work, at the Cook County Hospital in Chicago. Theoretically every burn might be considered as a sterilized wound, but practically it must be treated as an infected one on account of the contamination that must have occurred before it is seen by the physician. The problem is, therefore, to remove infective material and avoid the destruction of cells that are still living. Hence there should be no vigorous scrubbing with brush and strong soap, no application of powerful antiseptics, such as bichloride or cyanide of mercury, picric acid and phenol solution, etc. In a burn of the first degree, the papillary layer of the corium is intact, and the tactile bulbs being scarcely affected, the pain is not severe. The deeper epidermal layers will rapidly replace the damaged cells above them, if the former cells are not destroyed by strong antiseptics or by scrubbing.

The writer's technic for a burn of the first degree is described. As a prophylactic measure, all those employed by the Northwestern Elevated Railway Company are told not to apply to a burn anything but vaseline, and then to cover the burnt area with gauze before sending the patient to the hospital. The area beyond the burn is first cleaned of all grease and dirt by a fresh sponge soaked in ether, and gently applied also to the burnt surface, which is covered with an ointment of equal parts of cold cream and zinc oxide ointment, to which 5% white precipitate of mercury has been added. A sterile gauze compress and bandage is placed over this, and unless there is severe pain or a rise in temperature, this dressing is not removed until peeling has taken place. Bullae should be opened only if they cause pain by their tension. A gauze mask, with holes for eyes, nose and mouth, is to be used as a dressing for the face. In the hospital the open-air treatment is to be preferred, screen cages being used for burns of the extremities. Stearate of zinc or bismuth powder is all the dressing that need be applied.

In burns of the second degree the pain may be intense and the whole surface of the epidermis destroyed, leaving the bleeding papillae and terminal nerve bulbs exposed. The question

arises whether the wound shall be left to heal by connective tissue formation alone, thus producing a scar, or whether grafts must be used to replace the burnt epithelial cells; and this question must be answered by the location of the burn and by cosmetic considerations. All second-grade burns of face, neck and hands, or feet, or when situated in the vicinity of joints, must be grafted. The relief of the pain caused by the exposure of the nerve-endings is obtained by some protective covering, such as amniotic grafts, plain vaseline, or the ammoniated mercury ointment described above.

The summary of the writer's experience is as follows:

1. Leave burns of the first degree to nature as far as possible.
2. In burns of the second degree, decide early whether to resort to skin grafting; if deemed necessary, apply the grafts as soon as shock has abated, even in the presence of pus.
3. The open-air treatment of burns of all degrees gives the best results.
4. If the open-air treatment is impossible to follow out, apply a bland non-adherent dressing, and leave it on as long as possible.
5. In all second and third degree burns, pain must be overcome by protecting the exposed tactile bulbs. Amniotic membrane, or a bland, non-irritating ointment will give the best results.

#### X-RAY TREATMENT OF SCALP RINGWORM.

Mackie and Remer<sup>2</sup> of Columbia University, who have previously published a technic for measuring the quality and quantity of the x-ray, with a discussion regarding the value of the pastilles of platino-cyanide of barium, publish in the *Medical Record* the results of their experience in treating scalp ringworm with the x-rays. This affection varies curiously according to the geographical distribution, the Mississippi Valley, for instance, being almost exempt from it, while in New York it is quite common and extremely obstinate. The older methods, as epilation and strong antiparasitides, they consider ineffective in the case of the poorer classes, chiefly because it is found to be impracticable to carry out the treatment. Hence the disease remains more or less active until puberty, when it disappears spontaneously. The disease being contagious, the children are kept from school, and their education consequently neglected.

The value of the x-ray in this affection depends chiefly on its capacity for making the hair fall out. It does not essentially destroy the parasitic growth, although it may perhaps modify the soil so that the growth is inhibited. The greater part of the parasitic growth comes away with the hair, and the rest disappears or is destroyed by anti-parasitic treatment. The x-rays are applied either in the divided dose, as generally practised in America, or in the mas-

sive dose as advocated and employed in Europe to a great extent. The writers consider the divided-dose method unscientific and antiquated, in the treatment of ringworm of the scalp, as there is no accurate measurement, and the whole scalp cannot be epilated without considerable danger. It was in 1904 that Sabouraud and Noiré called attention to the application of the intensive method of treatment in scalp ringworm, and since then the disease has been treated in this way in almost all of the European clinics with such good effect that it has been almost eradicated from some of the cities.

The method adopted by the writers is not claimed as original, but has been the result of the work of many investigators. The essential points in the technic, which aims at complete depilation at a single sitting, are thus enumerated:

1. Cut the hair short. Indicate with a skin pencil five points—A, B, C, D and E—on the scalp, which are exactly five inches apart, and draw lines between the various points.

2. Apply an epilating dose (II I at skin distance, B 9 or 10) to each of the five points. Apply protection only to the face, ears, and neck. The vertical rays are aimed directly at the point under treatment and each exposure must be at right angles to the other exposures.

3. Measure the quantity accurately with a reliable radiometer. The quality must be estimated by means of some reliable penetrometer, such as the Benoist instrument, together with indirect methods such as the milliamperemeter, ammeter, etc.

4. The head must not move very much during the exposure. Absolute immobility is desirable.

This intensive method of treating ringworm of the scalp is accurate and scientific, but on account of the delicate technic it can be employed only by trained radiotherapists. The hair falls out at the end of about three weeks, and begins to grow in again in about three months. No irritating substances must be applied to the scalp for two to three weeks previous to this epilation or for a month after, when a 5% ointment of sulphur or ammoniated mercury or other mild parasiticide may be used. A linen cap is to be worn by the child while the hair is falling, to prevent the infection of other children. Some irritation may appear on the scalp a week or two after this treatment, or there may be a transitory erythema. A bad result and permanent alopecia indicates an error in technic. Occasional relapses occur, making it necessary to depilate a second time, and in such cases a period of about six months should be allowed to elapse. No cases of idiosyncrasy have been observed. The x-ray treatment of scalp ringworm cannot, however, be said to be wholly without danger; but the writers declare that if properly conducted, it is the best means we have

at present of quickly curing the affection; and the same is to be said of favus.
